The length of capillaries revealed a statistically significant difference ($P<0.02$–<0.005, Student's paired *t*-test) between tumor-bearing and control animals. The average capillary length in amelanotic melanoma was 198.2±8.9 µm on day 4 and 230.5±10.3 µm 8 days later (text-fig. 2). Capillary length in subcutaneous tissue of control tumor-free animals was 414.4±30.9 µm on day 4 and 418.5±21.8 µm on day 12, i.e., 14 days after implantation of the aluminum chamber.

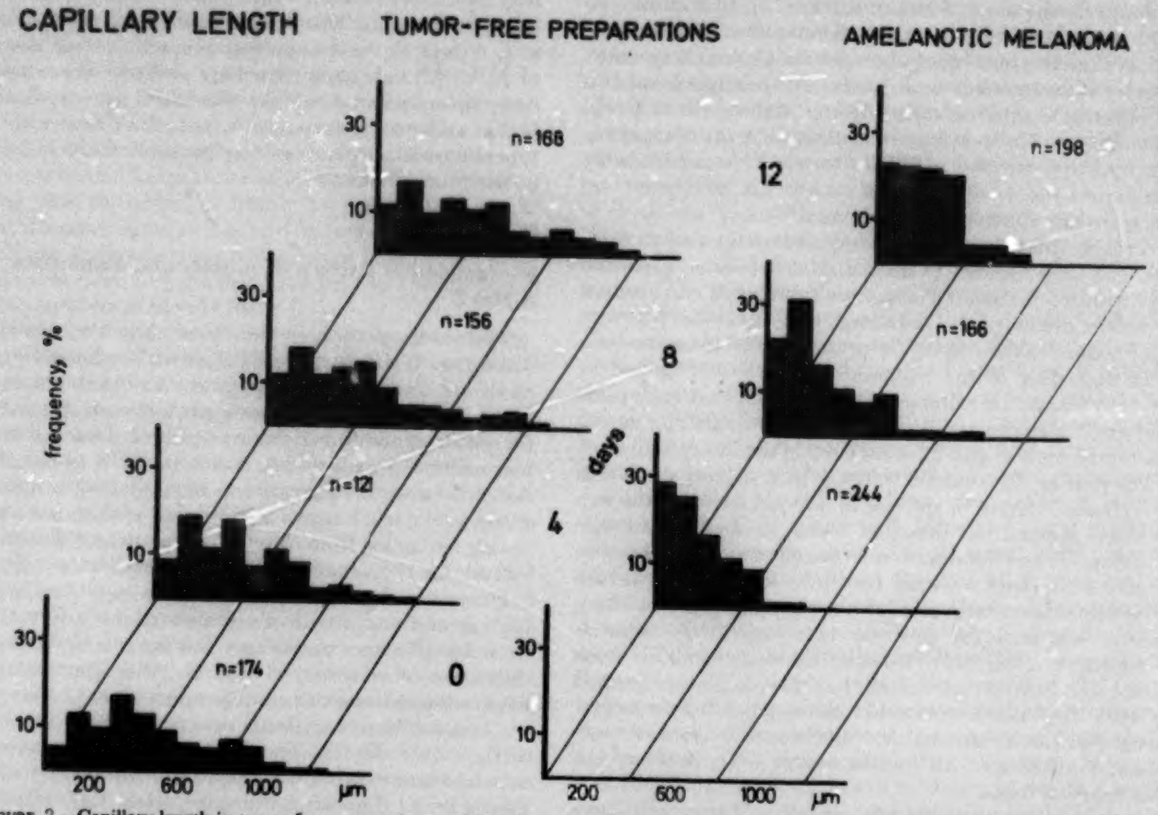
Large necrotic, avascular areas appeared in the center part of the tumor approximately 5 days after its transplantation. At that time, platelet conglomerates were consistently noted in capillaries of the amelanotic melanoma, temporarily blocking the blood flow. As the melanoma grew further, the vasculature continually pushed the existing microvascular channels toward the tumor's growing edge, while more centric blood vessels were obliterated.

On the basis of 71 determinations from 8 animals (control, $n=4$; A-Mel-3-bearing, $n=4$), a rise in capillary density was found in tumor-free control preparations, whereas in the tumor-containing chambers, the slight increase in the density of erythrocyte-perfused capillaries at 4 days after tumor transplantation was followed by a consecutive decrease as tumor growth continued (text-fig. 3).

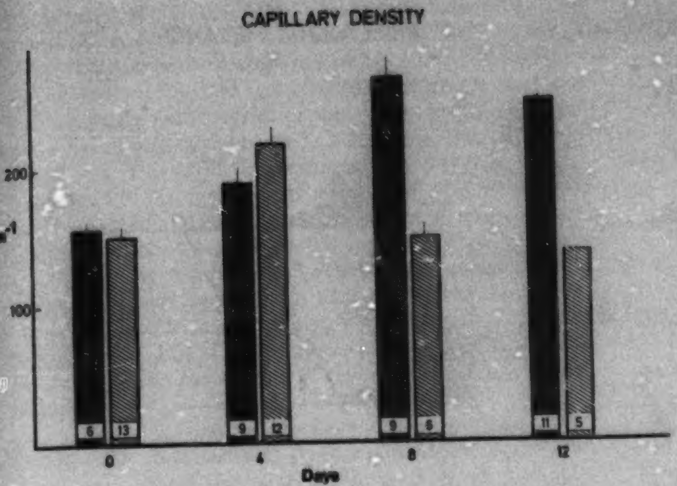
Hemodynamic Characteristics of Amelanotic Melanoma A-Mel-3

Table 1 demonstrates that, with the exception of a slight hypovolemia on day 0 in our control group, significant changes of mean arterial pressure, central venous pressure, and heart rate did not occur. The microcirculation of the amelanotic melanoma A-Mel-3, however, revealed typical alterations.

In most microvessels, the direction of blood flow *encircled* the center of the tumor, with intermittent or regurgitant blood flow in capillary channels. This phenomenon was strongly related to the presence of platelet conglomerates in tumor blood vessels. Tables 1 and 2 summarize measurements of blood cell velocity and vessel diameter at various days after tumor transplantation in amelanotic melanoma and in tumor-free control preparations. Mean blood cell velocity in capillaries was significantly different, and blood flow in single capillaries of the amelanotic melanoma A-Mel-3 revealed localized irregularities in those segments where microaneurysms or platelet conglomerates were observed. Despite the progressive dilation of arterioles and precapillaries, blood cell velocity in precapillaries of the tumor was significantly lower when compared to blood cell velocity in tumor-free preparations.



TEXT-FIGURE 2.—Capillary length in tumor-free preparations and in the amelanotic melanoma for various days after tumor cell transplantation. n=No. of determinations.



TEXT-FIGURE 3.—Capillary density in tumor-free preparations and in the amelanotic melanoma A-Mel-3. *Black columns* = tumor-free preparations; *hatched columns* = amelanotic melanoma A-Mel-3. *Hatched column* on day 0 reflects capillary density in the area subsequently transplanted with tumor cells. *Numbers within each column* are No. of determinations for a given day.

TABLE 1.—*Melanoma microcirculation: Parameters along different microvascular segments*[a]

Parameter	Day[a]			
	0	4	8	12
Mean arterial pressure, mm Hg	111.1±6.1	96.3±3.6	114.6±4.4	111.0±13.0

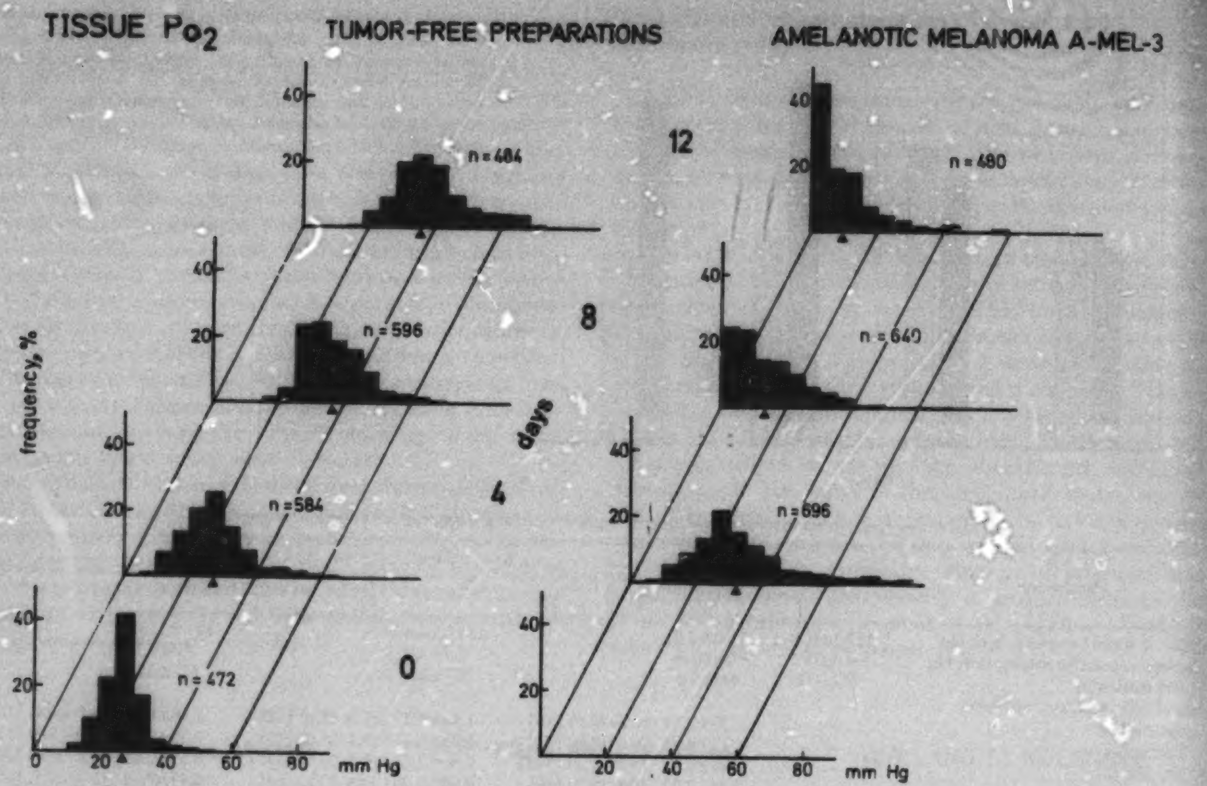
[a] Determinations were made at a local subcutaneous temperature of 30.1°C. Values are means ± SEM. *Numbers in parentheses* are ranges of diameters in micrometers. *Numbers in brackets* are No. of determinations.

After measuring blood cell velocity and diameter in each vessel supplying the tumor with blood, we calculated the volume flow through any inflow vessel and determined the total tumor blood flow. The mean blood flow of the amelanotic melanoma was 40.4 ml/minute/100 g on day 4 and 21.1 ml/minute/100 g on day 12, respectively. Further growth of the tumor resulted in large, unperfused areas in the amelanotic melanoma. Petechial hemorrhage developed in those segments where blood flow was re-established after a period of very slow (<0.10 mm/sec) or zero flow.

As a result of nonhomogeneous capillary perfusion, decreased capillary density, and central necrosis, the local tissue Po_2 decreased as the tumor grew. While the Po_2 histograms in subcutaneous tissue of tumor-free animals were homogeneous with a mean value between 20 and 35 mm Hg, the Po_2 histograms shifted to the left in all animals



TEXT-FIGURE 4.—Frequency distribution of local P_{O_2} for tumor-free preparations and for the amelanotic melanoma A-Mel-3 at days 0, 4, 8, and 12. n=No. of determinations as obtained by movement of the platinum multiwire electrode. Measurements were done in 12–15 different positions on the given tissue surface.

studied from earliest tumor growth throughout day 12. The P_{O_2} distribution in the sum histograms (text-fig. 4), with a mean value of 9.7±2.4 mm Hg on day 12, and the distinct change in skewness obtained in each animal reflect a progressive tissue hypoxia in the amelanotic melanoma A-Mel-3. This finding was not related to a difference in the number of single determinations.

DISCUSSION

For the prediction of antimalignant action of chemotherapy and radiation therapy in humans, preclinical screening systems are important because individual tumors, even those appearing identical by histologic grading, differ considerably in their response to treatment (*18*, *19*).

If human tumors were used in nude mice or hamsters, an experimental model could be designed to resemble human cancers biologically, immunologically, and genetically. However, host versus graft effects, particularly on the microvasculature, restrict this approach. From implanting pieces of different human tumors and small fragments of the amelanotic melanoma A-Mel-3, Witte and Goldenberg (*4*) concluded that homologous tumors are better adapted to the host's vascular system. When they used human tumor specimens, they noted, even in the immunologically privileged hamster cheek pouch, a pronounced reactive hyperemia in capillaries and larger blood vessels, a finding that is contrary to the established pathomechanism of capillary vascularization of a tumor mass (*1*, *2*, *4*, *20–22*). Consequently, human tumors cannot be used in animals for quantitative studies of the microcirculation within and around the transplant because "tumor-typical reactions" of the terminal vascular bed are most likely superimposed by the host versus graft reaction.

With a homologous tumor in the hamster's skin flap, distinct discrepancies of our blood cell velocity data, particularly at the arteriolar site, became apparent when these results were compared to data reported in the literature (*8*, *23*, *24*). However, recent studies on effects of anesthesia strongly suggest that anesthesia per se as well as the exposure of tissues affects most microvascular preparations and causes varying degrees of inflammation and vasodilation (*25*). Consequently, intravital microscopic exposure of tissues in the anesthetized animal very likely eliminates control mechanisms, namely, vasomotor activity (*26*). Contrary to current microcirculatory preparations, this phenomenon in our control animals was observed in about 60% of all arteriolar vessels studied (periodicity of this effect=2–3 cycles/min). Since data on blood cell velocity are usually reported as mean values for a certain period of time (20 sec in our study), the presence of vasomotor activity will yield lower blood cell velocities in arterioles. Furthermore, in contrast to our study, a great number of microcirculatory studies have been conducted with the local temperature adjusted to approximately 37°C (*8, 23, 24*). This temperature difference of approximately 7°C may provide another likely explanation for this apparent discrepancy in blood cell velocities.

It is a well-established fact that histograms of local Po_2 reflect perfectly the integrity of the microvascular network and the O_2 supply of the tissue (*27, 28*). The measurements of local Po_2 in control preparations and bell-shaped, homogeneous Po_2 histograms over a period of 12 days provide clear evidence of a normal, physiologic microcirculatory bed (*27, 28*) in our chamber model. The pattern of the capillary network and its flow characteristics, both quantitatively analyzable by the combination of local Po_2 measurements with the quantitative analysis of TV images, will directly affect the local Po_2. This combination is essential for the elucidation of the mechanism of tissue hypoxia in a malignant tumor.

Significant discrepancies between tumor-free and melanoma-bearing animals are 1) short, tortuous capillaries aligned only along the edge of the tumor; 2) capillary density/unit of tissue decreased as tumor grew while capillary density rose slightly in tumor-free preparations; 3) blood cell velocity at precapillary and capillary sites less in tumors than in subcutaneous tissues of tumor-free animals; and 4) lack of arteriolar vasomotion in the amelanotic melanoma. Moreover, any extravascular pressure on arteriolar tumor vessels results in both a complete stop of blood flow to the tumor center and a decrease of blood flow rate to large tumor areas, finally followed by necrosis. Low blood flow to large, central parts of the melanoma and higher blood flow to a very small volume of cells at the tumor's margin resulted in an overall decreased blood flow in the amelanotic melanoma A-Mel-3. Moreover, local variations in capillary morphology and alignment provide evidence that the tumor per se affects its blood supply (*20, 29–33*), a finding that could be quantitatively assessed by the measurement of capillary density.

The elevated capillary density 4 days after tumor transplantation and the subsequent, statistically significant decrease of this parameter indicate 1) tumor cell transplantation as a strong, angiogenic stimulus evoking an initial increase of capillary density (as a consequence, blood flow in the amelanotic melanoma A-Mel-3 was higher than that in subcutaneous tissue of tumor-free animals at the time of tumor development) and 2) significant effects of extravascular but intratumoral mechanical forces leading to a collapse of a great number of exchange vessels, hence reducing the overall rate of blood flow. One might argue that the decrease of capillary density in the tumor resulted from the given experimental conditions where the frame-to-frame distance of only 450 μm might apply external compression to the tumor. In fact, Eddy and Casarett (*22*) and Peters et al. (*29*) reported self-compression of "sandwich" tumors. Blood flow in their preparations could quickly be restored by an increase in the distance between the chamber frames. Peters et al. (*29*) reported that microcirculatory channels could not tolerate the sudden impact of resumed blood flow after ischemia; consequently, the area exposed was later covered with blood. Identical observations were made in our study, however, only after day 16 when the cover glass was removed. By contrast, during earliest tumor growth (days 0–12), when repeated opening and reinsertion of the cover glass were performed for measurements of local Po_2, microscopic inspection and quantitative analysis of blood cell velocity and capillary density before and after Po_2 measurements did not reveal any significant morphologic or microhemodynamic changes, thus indicating that our tumor was apparently not subjected to external compression until day 16 after tumor cell transplantation.

In particular, we never observed during the first 12 days of tumor development that blood flow or tumor volume (congestion of blood within the melanoma) increased when we lifted the cover glass. Consequently, any obstruction of capillary blood flow cannot result from external compression by cover glass or chamber frame but from "mechanical forces" within the proliferative system ("self-compression") of a malignant tumor because its microcirculation is characterized by a lack of organization, differentiation, and strictly correlated development of capillaries (*1–4, 22, 33*). Moreover, rarefaction and uneven distribution of capillaries within malignant tumors will inevitably cause local tissue hypoxia (*34, 35*).

A low capillary density, however, does not necessarily imply that the capillaries were not present. In fact, compression of larger microvascular entities associated with tissue hypoxia was frequently observed during tumor growth and was probably caused by an "internal tumor tissue pressure." This hypothesis can further be supported by 1) the fact that values of interstitial tissue pressure up to 23 mm Hg have been reported for the 7,12-dimethylbenz[*a*]-anthracene-induced adenocarcinoma of the rat (*36*); 2) the fact that, in the same tumor, the postcapillary and venular pressure was found to be significantly lower than that in subcutaneous tissue [a lower microvascular pressure might favor compression and obstruction of microscopic vessels in malignant tumors (*29, 36*)]; and 3) the finding of disintegration of the capillary endothelium and wide-open endothelial junctions in the amelanotic melanoma A-Mel-3 facilitating the filtration of fluid into the extravascular space (fig. 4).

These findings suggest that interstitial edema and proliferative activity in malignant tumors might compress a great number of nutritional capillaries. This "self-destroying capacity" may finally result in hypoxia or low-flow anoxia of large parts of the melanoma, whereas only a small tumor margin is still sufficiently supplied with blood.

Effect of Heating on Lethality Due to Hyperthermia and Selected Chemotherapeutic Drugs[1,2]

Terence S. Herman,[3,4] Cynthia C. Sweets,[3] David M. White,[3] *and* Eugene W. Gerner[5]

ABSTRACT—Because the rate of heating alters various cellular events associated with exposure to hyperthermia (including the rate of cell death), effect of this parameter on the cytotoxic interaction between selected anticancer drugs and hyperthermia was studied. The drugs cisplatin, 1,3-bis(2-chloroethyl)-1-nitrosourea, and adriamycin at 42.4°C and bleomycin and methotrexate at 43°C were tested in Chinese hamster ovary (CHO) cells in vitro. Heating times ranged from less than 3 minutes (immediate exposure) to 3 hours. For all drugs tested, synergistic cytotoxicity was not significantly altered by heating to peak temperature over 30 minutes as compared with immediate exposure. When heating to peak temperatures was prolonged to 3 hours, however, cell killing was markedly reduced, although significant sensitization to the drug remained. This was true despite the fact that, in CHO cells, heating to 42.4°C over 3 hours produced no cell killing for up to 6 hours at that temperature. These results suggested that the mechanism(s) responsible for induced thermotolerance are probably different from those that cause cellular resistance to the cytotoxic effects of the drugs tested. These results may also partially explain the relative lack of clinical success with whole-body hyperthermia and chemotherapeutic drugs as anticancer treatment, because heating to therapeutic temperatures often requires 2–3 hours.—JNCI 1982; 68: 487–491.

The treatment of cancer with chemotherapeutic drugs and hyperthermia has been stimulated by in vitro studies that have demonstrated markedly increased activity of several anticancer agents when used at clinically achievable hyperthermia temperatures (*1*). Our own pilot experiment utilizing whole-body hyperthermia in conjunction with anticancer drugs (*2*) was prompted by these observations. Our clinical work, however, revealed that whole-body heating to a peak temperature of 42.4°C required an average of about 170 minutes. Previously reported in vitro studies (*1, 3*) had employed heating techniques that were able to reach temperatures of 42–43°C within 3–5 minutes. Since this discrepancy seemed potentially important, we examined the rate of heating as a determinant of hyperthermic cytotoxicity. We found that cell survival over time at 42.4°C was dependent on the rapidity of heating to that temperature (*4*). We were also interested in determining whether the positive cytotoxic interaction between selected anticancer agents and hyperthermia would be altered by differing rates of heating. We can now report that this seems to be true for several chemotherapeutic drugs that we have tested with hyperthermia in CHO cells in vitro.

MATERIALS AND METHODS

Cell culture.—CHO cells, originally obtained in 1974 from Dr. Ronald M. Humphrey, University of Texas Cancer Center, M. D. Anderson Hospital, Houston, Tex., were grown in McCoy's 5-A medium supplemented with 20% (vol/vol) fetal calf serum, penicillin (11 U/ml), and streptomycin (100 μg/ml) (all from Grand Island Biological Co., Grand Island, N.Y.). Cells were maintained in logarithmic growth phase at 37°C in a 5% CO_2–95% air atmosphere. Doubling time was 13–14 hours for the CHO cells. Cell numbers were determined with an electronic particle counter (model ZBI; Coulter Electronics Inc., Hialeah, Fla.).

Cell viability measurements.—Cell viability was measured by the ability of single cells to form colonies in vitro, as described previously (*5, 6*). The colony-forming efficiencies of control cultures are between 85 and 95% for CHO cells. The results from colony-forming experiments, described in the text-figures, represent at least three replicate experiments per text-figure.

Heat treatments.—Exponentially growing cells were exposed to a peak temperature of 42.4°C or 43°C for 1 hour. In selected studies, the cells were taken from 37°C to peak temperature over times that varied from 30 minutes to 3 hours (rates of heating between 1.8°C and 12.0°C/hr). Other cells were exposed to 42.4°C or 43°C immediately (i.e., heated to peak temperature within 3 min). Heating was accomplished in a Plexiglas water tank with a continuous in-flow and out-flow system connected to a Haake model FK water heater. With this apparatus, the rate of heating could be adjusted so that continuous monitoring of bath temperature allowed different rates of heating, between 37°C and 42.4° or 43°C, to be achieved. Cells underwent heating in either T-25 or T-75 flasks (Falcon Plastics, Oxnard, Calif.) containing 5 or 15 ml, respectively, of fresh medium. Temperatures quoted are those of the cell monolayer position and were recorded with thermistor probes.

Drug treatments.—Exponentially growing cells were exposed to varying concentrations of BCNU (Bristol Laboratories Inc., Syracuse, N.Y.), *cis*-diamminedichloroplatinum(II) (cisplatin; Bristol Laboratories Inc., Syracuse, N.Y.), bleomycin (Bristol Laboratories Inc.), adriamycin (Farmitalia Co., Milan, Italy), or methotrexate (Lederle Laboratories, Pearl River, N.Y.) in 60-mm petri dishes for

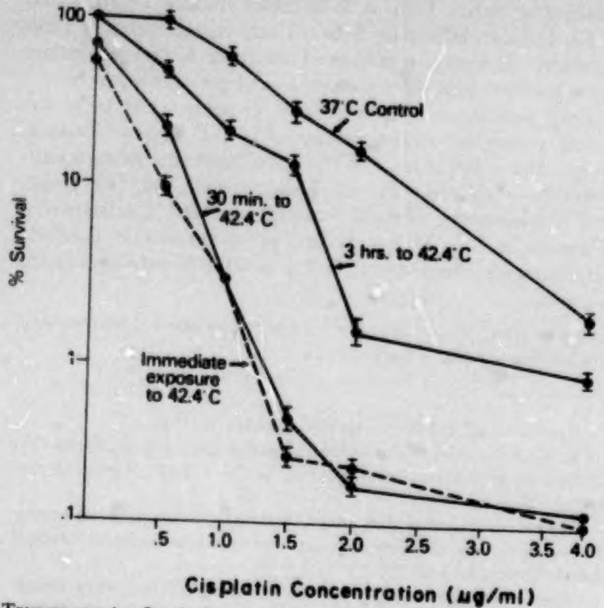
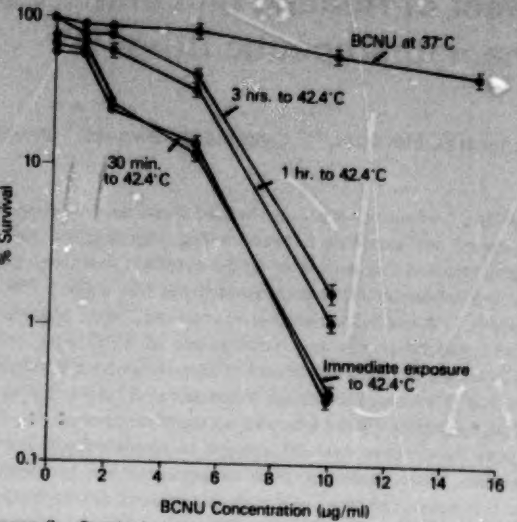
1 hour at 37°C or at 42.4° or 43°C in T-25 or T-75 flasks once cells had reached peak temperature. Small numbers of flasks were used so that all could be removed from the heating chamber, media poured off, and fresh media and drug added in less than 3 minutes by a team of investigators. Non-drug-treated controls were handled identically. We always prepared drug solutions immediately before use by dissolving the drug in sterile water (except for BCNU, which was dissolved primarily in 100% ethanol). Appropriate dilutions of drugs were added to fresh medium, with the volume of drug solution never exceeding 20% (1 ml) of the total volume of 5 ml. After treatment, the medium was removed and the cultures were washed twice with warmed Puck's Saline A (Grand Island Biological Co.) and trypsinized (0.05% for 2–3 min). Following this procedure, known numbers of cells were plated into plastic petri dishes for colony growth as described above.

RESULTS

Text-figure 1 depicts the effect of differing rates of heating on the cytotoxic interaction between cisplatin and exposure to 42.4°C for 1 hour. As compared with cell killing due to cisplatin at 37°C, cytotoxicity was strikingly enhanced when the 1-hour exposure to the drug occurred at 42.4°C if cells were rapidly heated to this temperature. At a drug concentration of 1 µg/ml, for instance, a 1-hour exposure at 37°C produced only about a 28% cell kill, whereas the same drug treatment at 42.4°C in cells heated over less than 3 minutes resulted in about a 96% cell kill. This is evidence of significant synergy, since immediate exposure to 42.4°C alone caused about a 25% cell kill, and simple additive lethality would have resulted in only about a 46% cell kill. Similarly, at other drug concentrations the resulting cell survivals indicated cytotoxic synergy between cisplatin and exposure to 42.4°C for 1 hour when heating from 37°C to 42.4°C occurred in 30 minutes or less. When heating of cells occurred over 3 hours, however, the cytotoxicity achieved by cisplatin and exposure to 42.4°C decreased. In this circumstance, after exposure to 1.0 µg/ml for 1 hour at 42.4°C, cell kill was only about 60% as opposed to about 96% when heating to 42.4°C was immediate. However, despite the fact that a 1-hour treatment at 42.4°C caused no cell kill if heating was accomplished over 3 hours, cells were still altered in a manner that increased significantly the cytotoxicity of cisplatin.



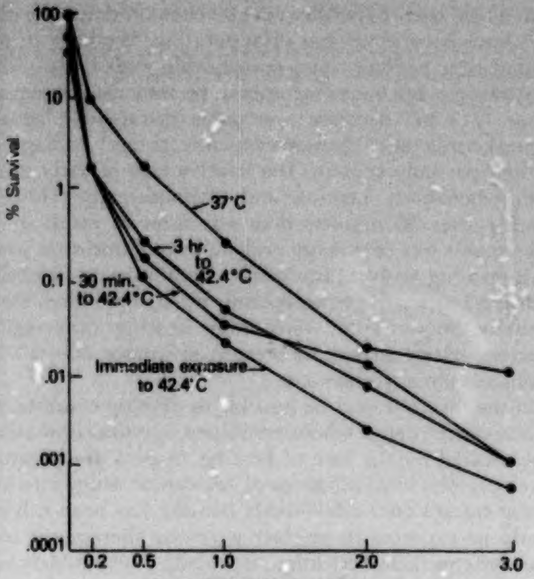
Text-figure 1.—Survival curve of exponentially growing CHO cells exposed to the concentrations of cisplatin indicated at 37°C or 42.4°C for 1 hr after heating times from 37°C to 42.4°C as indicated. *Bars* represent standard errors.



Text-figure 2.—Survival curve of exponentially growing CHO cells exposed to the concentrations of BCNU indicated at 37°C or 42.4°C for 1 hr after heating times from 37°C to 42.4°C as indicated. *Bars* represent standard errors.

Text-figure 2 shows the effect on cytotoxicity due to hyperthermia and BCNU when differing rates of heating to 42.4°C were used. As was true for cisplatin, significant cytotoxic synergism was observed between exposure to BCNU and 42.4°C for 1 hour. Heating times of 30 minutes or less produced the greatest synergy. At a concentration of 5 µg BCNU/ml, for instance, about an 85% cell kill occurred after a 1-hour exposure at 42.4°C if heating occurred over 30 minutes or less than 3 minutes, but only about a 60% cell kill was observed if heating occurred over 1 hour or 3 hours. Again, heating over 3 hours to 42.4°C, which resulted in no measurable cell kill in itself, did sensitize cells to BCNU.

When this same experiment was conducted with adriamycin, the effect of the rate of heating was more difficult to appreciate (text-fig. 3). Our CHO cells are extremely sensitive to relatively low concentrations of adriamycin at 37°C as we have previously reported (*7*). Exposure to adriamycin at 42.4°C, however, did result in significantly increased cytotoxicity above that attributable to a simple additive effect. For instance, cell kill following exposure to 0.2 µg adriamycin/ml for 1 hour at 37°C was 90%. A 92.5% cell kill would have been expected to have resulted from an additive interaction between immediate heating to 42.4°C



TEXT-FIGURE 3.—Survival curve of exponentially growing CHO cells exposed to the concentrations of adriamycin indicated at 37°C or 42.4°C for 1 hr after heating times from 37°C to 42.4°C as indicated. Largest standard error=±0.8%. Cell survivals after exposure to 42.4°C and these doses of adriamycin are significantly different for heating times of 3 hr as compared with immediate exposure [$P<0.01$ by the nonparametric Wilcoxon test (*7*)].

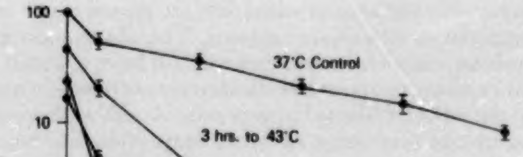
for 1 hour and this concentration of adriamycin. Instead, however, about a 98% cell kill was observed. When heating to 42.4°C occurred over 3 hours or 30 minutes, somewhat less cell kill occurred throughout the dose range of adriamycin used. Clear differences between the cytotoxicity caused by adriamycin and 1-hour exposure to 42.4°C when heating occurred over 3 hours or 30 minutes were not observed (error bars have been omitted for ease of presentation). A significant decrease, however, was seen between the cell kill caused by 1-hour exposures to these concentrations of adriamycin at 42.4°C if heating to this temperature required 3 hours as opposed to less than 3 minutes [$P<0.01$ by the nonparametric Wilcoxon test (*8*)].

We also examined cell killing due to bleomycin and methotrexate at 43°C in relationship to the rate of heating (text-figs. 4, 5). In text-figure 4 cell survivals graphed on the *y* axis show the effect of hyperthermia alone and demonstrated that the rate of heating altered cell killing due to a 1-hour exposure to 43°C as well as 42.4°C. Instead of about an 80% cell kill due to exposure to 43.0°C for 1 hour when heating was immediate, heating over 3 hours resulted in only about a 50% cell kill. No significant reduction in the synergistic cytotoxicity due to the dose range of bleomycin employed and exposure to 43°C for 1 hour was appreciated when heating occurred over 30 minutes as compared with immediate heating. When heating time was 3 hours, however, the cell kill achieved was markedly reduced. For instance, only about an 80% cell kill occurred after exposure to 1 µg bleomycin/ml for 1 hour at 43°C when heating was conducted over 3 hours as opposed to a 95% celi kill when heating time was 30 minutes or less than 3 minutes. At other concentrations of bleomycin, a similar pattern was observed. As with the other drugs, however, except for cell survival after 1 µg/ml in cells heated over 3 hours to 43.0°C where lethality was roughly additive, cell killing due to higher concentrations of bleomycin at 43.0°C for 1 hour remained greater than additive even when heating occurred over 3 hours.

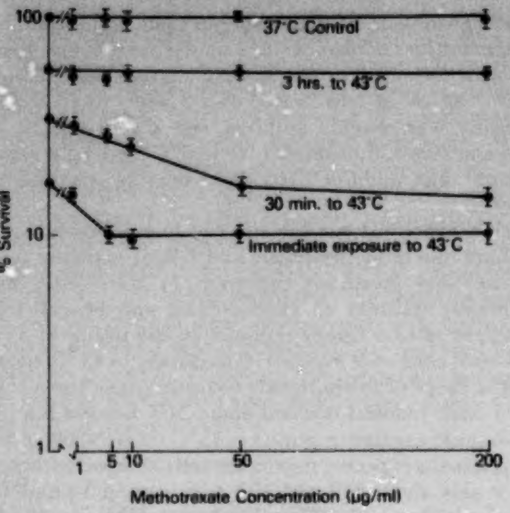
Text-figure 5 shows the effect of rate of heating on cytotoxicity due to methotrexate and 1-hour exposure to 43°C. As we have previously reported (*7*), our CHO cells are extremely resistant to methotrexate and no cell kill was observed after a 1-hour exposure to 200 µg/ml at 37°C. If, however, cells were exposed immediately to 43°C, treatment with a range of methotrexate concentrations above 5 µg/ml for 1 hour reduced survival about 50% beyond that due to a 1-hour immediate exposure to 43°C (from ≈20% to ≈10%). This was the expected maximum cell kill from methotrexate, since only about 50% of CHO cells were in S-phase during exponential growth. When heating to 43°C was conducted over 3 hours, however, no increase in cell kill over that due to hyperthermia (≈50%) was caused by methotrexate over the dose range tested. When heating time was 30 minutes, an interesting survival pattern was observed. Cells surviving hyperthermia seemed partially sensitized to methotrexate so that only at 50 and 200 µg/ml concentrations did a 1-hour exposure to methotrexate result in a full 50% additional cell kill.

DISCUSSION

We have demonstrated in our in vitro system that the magnitude of cell killing due to hyperthermia and selected anticancer drugs is partially dependent on the rate of heating from 37°C to peak temperature. We have previously reported (*4*) that the killing in CHO cells due to exposure



TEXT-FIGURE 4.—Survival curve of exponentially growing CHO cells exposed to the concentrations of bleomycin indicated at 37°C or 43.0°C for 1 hr after heating times from 37°C to 43.0°C as indicated. *Bars represent standard errors.*



TEXT-FIGURE 5.—Survival curve of exponentially growing CHO cells exposed to the concentrations of methotrexate indicated at 37°C and 43.0°C for 1 hr after heating times from 37°C to 43.0°C as indicated. *Bars* represent standard errors.

to 42.4°C over time is dependent on the rate of heating from 37°C. We were able to correlate these survival differences with an increase in total cellular protein within the particulate fraction of cells heated to temperatures over 3 hours, whereas rapidly heated cells showed a significant reduction in protein. In addition, slowly heated cells showed no significant change in size or cholesterol content, while rapidly heated cells showed marked fluctuations over time at peak temperature in these indirect measures of plasma membrane integrity (*9*).

We have not reported studies here of drug uptake in slowly heated cells as compared with rapidly heated cells, but preliminary investigations indicate that uptake is decreased with adriamycin when cells are heated over 3 hours as opposed to immediate exposure. This observation is not surprising, since Hahn and Strande (*10*) have reported that prior exposure to hyperthermia decreases adriamycin uptake into their HA1 Chinese hamster cells. A similar decrease in drug uptake may occur for other drugs after slow heating, even for drugs whose synergistic cytotoxicity with hyperthermia is not due to increased drug entry (*10*). Alternatively, drug access to cellular sites of action or cellular repair capabilities may also be affected by the rate of heating to hyperthermic temperatures.

It is intersting to us that although the combined cytotoxicities of selected chemotherapeutic drugs and hyperthermia are reduced by slow heating to peak temperature, sensitization to the drugs is not eliminated. Even in cells that were heated over 3 hours to 42.4°C and had become fully thermotolerant, significantly increased drug-induced lethality was apparent. These observations suggest that the induction of thermotolerance probably occurs by mechanisms that are separate from those responsible for resistance to the cytotoxic actions of these drugs.

While it is difficult to extrapolate from in vitro data to clinical results, reported response rates in patients treated with whole-body hyperthermia and chemotherapeutic drugs (*12*) have been somewhat disappointing. We have demonstrated that heating times comparable with those usually necessary to raise core temperature into the therapeutic range (2–3 hr) decrease synergistic cytotoxicity between hyperthermia and chemotherapeutic drugs. Perhaps this finding partially explains the relative lack of early success with whole-body heating and chemotherapy. However, heating over 30 minutes does not seem to result in any appreciable loss of synergy and we have found that whole-body heating to 42°C from 37°C in 30 minutes is possible utilizing heating of extracorporally circulated blood. Unfortunately, more rapid whole-body heating may lead to greater toxicity as well as greater antitumor effects as we may have already observed.

In the future it may be possible to develop combinations of anticancer drugs whose combined cytotoxicities will be less affected by the rate of heating to peak temperatures. Alternatively, local infusions of anticancer drugs into large tumor masses once whole-body heating has been achieved would be expected to produce a greater therapeutic index than systemic administration, especially if whole-body heating occurs slowly since sensitization to drug would be expected to be preserved while toxicity from hyperthermia in normal tissues should be minimized. It may also be possible that slow heating to lower hyperthermic temperatures in the range of 41–41.5°C for sustained times may result in a greater therapeutic index. In this regard the work of Read et al. (*13*) may be pertinent. These investigators have demonstrated that CHO cells heated at 41–42°C for prolonged periods show the loss of thermotolerance after about 18–20 hours. Cell killing then proceeds exponentially. Delayed administration of drugs until this time may also provide greater therapeutic benefit and needs to be studied preclinically. Finally, the data we have reported would suggest that the use of selected chemotherapeutic drugs with regional-local hyperthermia should be very effective since rapid heating times are possible.

Glutathione *S*-Transferase Activity: Enhancement by Compounds Inhibiting Chemical Carcinogenesis and by Dietary Constituents[1,2,3]

Velta L. Sparnins,[4] Placida L. Venegas,[4] *and* Lee W. Wattenberg[4]

ABSTRACT—Benzyl isothiocyanate, β-naphthoflavone, coumarin, α-angelicalactone, disulfiram, indole-3-carbinol and indole-3-acetonitrile induced increased glutathione (GSH) *S*-transferase activity in the liver and small intestine in female ICR/Ha mice. All seven compounds are inhibitors of chemical carcinogenesis. In additional work, several dietary constituents increased GSH *S*-transferase activity. Consumption of diets containing dried powdered preparations of brussels sprouts, cabbage, coffee beans, or tea leaves resulted in increased GSH *S*-transferase activity. Mice fed an unrefined diet (Purina Rat Chow) had a higher GSH *S*-transferase activity than those fed a semipurified diet. The results of the present study indicated that the composition of the diet can alter the activity of an important enzyme system having the capacity to detoxify chemical carcinogens.—JNCI 1982; 68:493–496.

An increasing number of compounds have been found to inhibit the neoplastic effects of chemical carcinogens when these compounds are administered before and/or simultaneously with exposure to the carcinogen (*1–3*). One of the most effective compounds of this type is 2(3)-BHA, which inhibits a wide range of chemical carcinogens (*2*). Studies by Benson et al. (*4, 5*) have shown that 2(3)-BHA administered in the diet markedly increased GSH *S*-transferase activity. The greatest effect was on the GSH *S*-transferase activity of the liver, which was enhanced eightfold. Smaller increases were found in other tissues. Ethoxyquin, which suppresses BP-induced neoplasia, also was found to enhance GSH *S*-transferase activity (*4*).

GSH *S*-transferase has been studied extensively as a major detoxification system that catalyzes the binding of various electrophiles to GSH (*6, 7*). Since the reactive ultimate carcinogenic forms of chemical carcinogens are electrophiles, GSH *S*-transferase takes on considerable importance as a mechanism for carcinogen detoxification. Enhancement of the activity of this system potentially could increase the capacity of the organism to withstand the neoplastic effects of chemical carcinogens. Experiments have been performed to determine if there is a relationship between increased GSH *S*-transferase activity in a target organ of chemical carcinogenesis and response to the carcinogen. For this purpose, the forestomach of the mouse was used. Members of several classes of inhibitors of BP-induced neoplasia of the mouse forestomach were studied for their effects on the GSH *S*-transferase activity in that structure. Five of the compounds increased the GSH *S*-transferase activity of the forestomach between 78 and 182%. The five compounds were *p*-methoxyphenol, 2-BHA, coumarin, α-angelicalactone, and benzyl isothiocyanate. All five inhibited BP-induced neoplasia of the forestomach. These data indicate that enhancement of the GSH *S*-transferase activity by an amount of about 75% or greater is associated with a reduced carcinogenic response of the forestomach to BP (*8*). The data also suggest that the capacity to enhance GSH *S*-transferase activity might be used as a method of identifying compounds or natural products likely to inhibit BP or other carcinogens detoxified in a similar manner.

In many instances carcinogens are consumed in the diet and have target sites of action in organs such as lung or breast, which are distant from the gastrointestinal tract. Under these conditions, the carcinogen could be detoxified in the small intestine and liver. The reaction of the liver and small bowel to a particular inducer of increased GSH *S*-transferase activity and that of the forestomach may be very different. Thus 3-BHA is a potent inhibitor of GSH *S*-transferase activity of the liver and small bowel but is weak for forestomach (*4, 5, 8*). The liver and the small intestine have high levels of GSH *S*-transferase activity and also show very marked increases in GSH *S*-transferase activity in response to appropriate inducers. Thus the levels of GSH *S*-transferase activity in liver and small bowel could be exceedingly important for the response of many tissues to exposures to chemical carcinogens. In the present work the effects of several inhibitors of carcinogen-induced neoplasia of tissues distant from the alimentary tract have been studied on the GSH *S*-transferase activity of small bowel mucosa and liver. These inhibitors included benzyl isothiocyanate, β-naphthoflavone, coumarin, α-angelicalactone, disulfiram, indole-3-carbinol, and indole-3-acetonitrile (*3, 9–15*). In addition, the effects of some natural products on GSH *S*-transferase activity have been ascertained.

MATERIALS AND METHODS

Animal experiments.—Female ICR/Ha mice from the Madison, Wis., facility of the Harlan-Sprague-Dawley Co., Indianapolis, Ind., were used in all experiments. Mice were randomized by weight at 7 weeks of age. At that time they were divided into groups of 5 to 10 animals each and placed on experimental diets. A semipurified diet was given consisting of 27% vitamin-free casein, 59% starch, 10% corn oil, 4% salt mix (U.S. Pharmacopeia XIV) and a complete

mixture of vitamins (Teklad, Inc., Madison, Wis.). To this semipurified diet were added the test compounds. In experiments comparing the semipurified diet with an unrefined diet, pulverized Purina Rat Chow (Ralston Purina Co., St. Louis, Mo.) was used. Inhibitors were employed in concentrations shown to inhibit carcinogen-induced neoplasia. Inactive compounds were used in concentrations for which they were shown to lack carcinogen-inhibitory capacities. The diets were fed for 2 weeks, at which time the mice were killed. The liver and proximal half of the small bowel were removed. The small bowel was opened and washed, and the musosa was scraped off gently.

Preparation of homogenates and cytosol.—All steps were done at 0-4°C. The tissues to be studied were homogenized in 0.1 *M* phosphate buffer (pH 7.5). The homogenate was centrifuged at 9,000×*g* for 20 minutes and then at 100,000×*g* for 1 hour. The supernatant was used for the assay of GSH *S*-transferase activity.

Determinations of GSH S*-transferase activity.*—The activity of cytosol GSH *S*-transferase was determined spectrophotometrically at 30°C with 1-chloro-2,4-dinitrobenzene as substrate according to the procedure of Habig et al. (*16*). The reaction mixture (1 ml) contained 100 μmol phosphate buffer (pH 6.5), 5 μmol GSH, and 1 μmol 1-chloro-2,4-dinitrobenzene. The reaction was started by addition of cytosol.

Chemicals.—Benzyl isothiocyanate was obtained from Eastman Organic Chemicals (Rochester, N.Y.); β-naphthoflavone, disulfiram, coumarin, α-angelicalactone, umbelliferone, γ-valerolactone, indole-3-carbinol, indole-3-acetonitrile, and 1-chloro-2,4-dinitrobenzene were from Aldrich Chemical Co. (Milwaukee, Wis.); 2(3)-BHA was purchased from Sigma Chemical Co. (St. Louis, Mo.). 3-BHA was prepared from the commercially obtained 2(3)-BHA by recrystallization from acetone as described previously (*17*).

Natural products.—Green coffee beans from Guatemala were purchased from the McGarvey Coffee Company (Minneapolis, Minn.). Chieftain Savoy variety cabbage and Jade Cross variety brussels sprouts were grown on the St. Paul campus of the University of Minnesota without use of chemical pesticides. Bulk black tea leaves from Ceylon were obtained from Coffee & Tea, Ltd. (St. Paul, Minn.). A commercial brand of instant tea, Lipton Co., Englewood Cliffs, N.J. was used. For addition to the diet, the green coffee beans, vegetables (after chopping and air drying), and tea leaves were converted to a powder form in a Waring Blendor.

RESULTS

All of the compounds that have been shown to protect against chemical carcinogenesis induced an increase in GSH *S*-transferase activity. These included 3-BHA, β-naphthoflavone, disulfiram, α-angelicalactone, coumarin, indole-3-carbinol, and indole-3-acetonitrile (table 1). In contrast, three compounds ineffective as inhibitors of carcinogen-induced neoplasia, i.e., tetrafluorophenol, γ-valerolactone, and umbelliferone, did not induce increased GSH *S*-transferase activity. Compounds inducing increased activity invariably did so in both tissues. The two lactones α-angelicalactone and coumarin and indole-3-acetonitrile have a more potent effect on liver than on the small bowel.

The results of studies of effects of natural materials and dietary constituents on GSH *S*-transferase activity are recorded in experiments 5-8 in table 1. Substituting an unrefined commercial diet (Purina Rat Chow) for the semipurified diet resulted in enhancement of GSH *S*-transferase activity. Cabbage produced a similar magnitude of enhancement and brussels sprouts and tea leaves caused a greater induction. Of the natural products tested, the largest effect occurred with green coffee beans. The increase in GSH *S*-transferase was particularly prominent in the mucosa of the small bowel. The green coffee beans caused the greatest enhancement of GSH *S*-transferase activity in the mucosa of the small bowel of any of the test substances studied.

DISCUSSION

The results of the present study show that diverse groups of compounds having the capacity to inhibit carcinogen-induced neoplasia all induce an increase in GSH *S*-transferase activity in liver and the mucosa of the small bowel (*3, 9-15*). Compounds inducing increased GSH *S*-transferase activity have been found to have other biological effects as well. The best studied of these compounds is 3-BHA, which has been shown to increase the activity of UDP-glucuronosyl transferase, epoxide hydrolase, and NADPH:quinone reductase and also to alter the microsomal metabolism of BP (*2, 18-24*). The data obtained in the present investigation show an association between inhibition of carcinogen-induced neoplasia and induction of increased GSH *S*-transferase activity. However, it is not clear whether induction of GSH *S*-transferase is directly or partially responsible for inhibition of neoplasia, or represents a marker parameter.

In previous studies, consumption of crude diets was found to increase AHH activity. This induction was shown to be due to xenobiotic compounds of vegetable origin (*25, 26*). Since both AHH and GSH *S*-transferase are involved in the metabolism of foreign compounds, the question arose as to whether crude diets would also enhance GSH *S*-transferase activity. In the present investigation, mice fed Purina Rat Chow had a higher GSH *S*-transferase activity than those fed a purified diet. The inducing compound or compounds in the Purina Rat Chow have not been identified. In addition to the crude diet, brussels sprouts and cabbage were investigated. These two vegetables contain indoles and aromatic isothiocyanates, compounds that induce increased GSH *S*-transferase activity (*26-28*). Both of these vegetables were found to enhance GSH *S*-transferase activity. Coffee beans also were investigated in the present study. Consumption of green coffee beans resulted in exceedingly high levels of GSH *S*-transferase activity. Subsequently, tea was studied. It also had inducing capacity but was less potent than coffee. Work is in progress aimed at the identification of the active constituent in these two materials. The enhancement of GSH *S*-transferase activity by natural products is of interest because it suggests that one way in which the composition of the diet may alter responses to chemical carcinogens is by enhancing GSH *S*-transferase activity and/or associated detoxification systems.

TABLE 1.—*Effects of β-naphthoflavone, disulfiram, benzyl isothiocyanate, phenols, lactones, coumarins, indoles, green coffee beans, vegetables, instant tea, and tea leaves on the GSH S-transferase activity in the cytosols of mouse liver and mucosa of the small intestine*

Organ-Specific Promoting Effects of Phenobarbital Sodium and Sodium Saccharin in the Induction of Liver and Urinary Bladder Tumors in Male F344 Rats[1,2,3]

Keisuke Nakanishi,[4] **Shoji Fukushima,**[4] **Akihiro Hagiwara,**[4] **Seiko Tamano,**[4] *and* **Nobuyuki Ito**[4,5]

ABSTRACT—Studies were conducted to determine whether initial treatment with *N*-2-fluorenylacetamide (2-FAA) or *N*-butyl-*N*-(4-hydroxybutyl)nitrosamine (BBN) followed by treatment with either phenobarbital sodium (PB) or sodium saccharin (SS) induced or enhanced liver and/or bladder tumorigenesis. Male inbred F344 rats were given 0.05% PB and 5.0% SS in the diet for 32 weeks after 4-week administration of 0.02% 2-FAA or 0.01% BBN. PB significantly enhanced hepatocarcinogenesis after 2-FAA treatment and induced hyperplastic liver nodules after BBN treatment. The SS significantly enhanced induction of bladder hyperplasias, but not papilloma after BBN treatment, and induced bladder hyperplasias after 2-FAA treatment. However, PB had no effect on the bladder and SS had no effect on the liver after either 2-FAA or BBN treatment. The data indicate that although 2-FAA and BBN have tumor-initiating effects in the liver and urinary bladder, the tumor-promoting effects of PB and SS are organ-specific. The tumor-promoting effect of PB for the liver is relatively greater than that of SS for the urinary bladder.—JNCI 1982; 68:497–500.

The two-stage process of carcinogenesis involving initiation and promotion has been demonstrated in the skin (*1, 2*) and in various organs, such as the liver (*3–7*), urinary bladder (*8–10*), breast (*11, 12*), colon (*13*), lung (*7, 14*), and stomach (*15, 16*), with a variety of chemicals used as initiating and promoting agents. Whether the initiating and/or the promoting agent is responsible for organ specificity is presently unclear (*17*). It has been established that cancer in humans and other animals can be induced by a multistage process and that cofactors play a role in cancer induction (*18*).

It has been shown that 2-FAA has carcinogenic activity toward various organs in rats including the liver and urinary bladder (*19*). BBN induced tumors only in the urinary tract, especially the urinary bladder, in rats (*10, 20*). However, several carcinogens not specific for the liver combined with partial hepatectomy have been shown to act as initiators in the liver and induce liver neoplasia in rats when promoting agents are subsequently administered (*4, 5*). We concluded, therefore, that BBN may also have initiating activity in the liver.

It has been shown that PB (*3, 6*) and SS (*8–10*) act as promoters for the liver and urinary bladder, respectively, if administered after initiation. However, the promoting effect of PB or SS on the induction of both liver and bladder tumors and the direct comparison of the promoting effect of PB for the liver and of SS for the bladder have not been evaluated. In the present experiment, the promoting effect of PB or SS for the liver and bladder was evaluated following initiation with either 2-FAA or BBN.

MATERIALS AND METHODS

Chemicals—2-FAA was purchased from Nakarai Chemical, Kyoto; BBN from Izumi Chemical Co., Yokohama; SS, containing 7 ppm orthotoluenesulfonamide, from Okuno Chemical Co., Osaka; PB from Iwaki Pharmaceutical Co., Tokyo; and Tween 80 from Katayama Chemical Co., Osaka.

Animals and experimental design.—A total of 272 male inbred F344 rats (Charles River Japan Co., Kanagawa) weighing 100–120g were divided into 3 groups. These groups were further separated into 3 subgroups (A–C) for testing on PB, SS, or control diet.

Group 1: Rats were fed basal diet (Oriental M; Oriental Yeast Co., Tokyo) containing 0.02% 2-FAA for 4 weeks and then given 0.05% PB (A), or 5.0% SS (B) in the diet, or basal diet (C).

Group 2: Rats were given 0.01% BBN in the drinking water containing 0.01% Tween 80 for 4 weeks followed by the treatments for subgroups A, B, and C as described for group 1.

Group 3: Rats were fed untreated diet and water for 4 weeks followed by the treatments for the 3 subgroups as described for group 1. All subgroups consisted of 30 rats except subgroups 1B and 2B, which consisted of 31 rats at the start of the experiment.

Rats were housed 5/cage in plastic cages in an airconditioned room at 24°C with 50% humidity and were weighed weekly. Food and water consumption were determined periodically during the experiment. Animals that died during the experimental period were autopsied and examined, but they were not included in the final count.

Histologic observation.—All rats were killed with ether at the end of week 36. Their urinary bladders were inflated with 10% phosphate-buffered Formalin solution via the urethra

and removed. The liver, both kidneys, and the spleen were also removed and weighed and fixed in the same fixative solution. The liver lobes were cut off and cut into serial sections 2–3 mm thick. Several of these sections were prepared for histologic examination. When gross nodular lesions were observed in a few serial sections, the section in which the nodule was largest was examined. The urinary bladder was cut into left and right halves, and six to eight serial sections were cut from each half. All tissue sections were stained with hematoxylin and eosin. Other tissues with abnormalities by gross examination were also examined histologically.

Cross sections of each liver lobe were prepared for histologic examination. Proliferative lesions of parenchymal cells greater than 0.2 mm in diameter were classified as hyperplastic nodules. Relatively large nodular areas with a trabecular or papillary structure and cytological atypia were classified as hepatocellular carcinomas. For quantitative analysis of these lesions (number and total area per 1 cm^2 of liver specimen), a general purpose color image processor (model VIP-21C; Olympus-Ikegami Co., Tokyo) was used as described previously (*21*).

Serial sections of the urinary bladder were prepared for histologic examination. Histologic changes of the urinary bladder were classified into four types: simple hyperplasia, papillary or nodular hyperplasia, papilloma, and cancer. The average numbers of all these lesions except simple hyperplasia per 10-cm length of basement membrane was calculated for each group with a divider or the color image processor as described previously (*10*).

The data were subjected to analysis of variance, and differences between means were tested by Student's *t*-test. Comparison between groups was made by the χ^2-test.

RESULTS

All rats except those given 2-FAA or SS gained weight at rates similar to those of the control group (group 3C). Some rats died of pneumonia or other causes during the experiment. Liver or bladder lesions were seen in few of these rats and no other neoplastic lesions were found. The intake of chemicals did not differ for the different groups, and the average consumptions of 2-FAA, BBN, PB and SS were approximately 7–11, 10–15, 23–33, and 2,000–3,000 mg/kg/day, respectively. However, water intake was about 50% greater per kilogram body weight in groups of rats given SS compared to water intake in other groups.

Liver Changes

Gross white spots or masses were frequently seen on the liver surface in the group treated with 2-FAA (group 1), especially subgroup B, and the liver was enlarged in rats given PB (all subgroups A). Findings in the liver for each group are shown in table 1.

In the groups pretreated with 2-FAA (group 1), almost all rats (93–100%) had hyperplastic nodules. In group 1A, treated with PB after 2-FAA, hepatocellular carcinomas were seen in 5 of 24 rats (21%), but no metastases were observed. The average numbers and areas of hyperplastic nodules per 1 cm^2 of liver in group 1 A were significantly higher ($P<0.05$) than those in the group treated with 2-FAA alone (group 1C). However, no significant differences in the liver were seen between groups 1B and 1C. The incidence, average number, and area of hepatocellular carcinomas per 1 cm^2 of liver specimen in the group treated with 2-FAA and then PB (group 1A) were significantly higher ($P<0.05$, $P<0.01$, and $P<0.05$, respectively) than those in the group treated with 2-FAA alone (group 1C). Although treatment with BBN alone (group 2C) or PB alone (group 3A) induced no liver lesions, sequential administration of these two chemicals (group 2A) resulted in a significant ($P<0.01$) incidence of hyperplastic nodules. However, the number and the area of the nodules per liver were negligible. Cholangiofibrosis was seen in group 1 (table 1). Other liver lesions seen were oval cell proliferation and cystic change of the bile ducts in group 1, and bile duct proliferation and fatty change in all subgroups A. No specific changes were observed in other groups treated with BBN and/or SS or in control rats.

Urinary Bladder Changes

In group 2, initially treated with BBN, we observed gross papillary lesions extending into the bladder lumen. The average length of the basement membrane was 11–14 cm in each subgroup. Findings in the urinary bladder are summarized in table 2.

Although treatment with 2-FAA (group 1C) or SS (group

[c] *P*<0.01, compared with subgroup C (basal diet).

3B) alone induced no lesions in the urinary bladder epithelium, sequential administration of these two chemicals (group 1B) resulted in a significant (*P*<0.05) incidence of simple hyperplasia and papillary or nodular hyperplasia. However, the average number of papillary or nodular hyperplastic lesions was not significantly increased. Treatment with PB after initiation with 2-FAA (group 1A) had no significant effect on the urinary bladder epithelium.

In group 2, pretreated with BBN, three types of epithelial changes—simple hyperplasia, papillary or nodular hyperplasia, and papilloma—were seen in the urinary bladder epithelium. However, carcinoma was not observed in any of the groups in this experiment. Treatment with SS after BBN (group 2B) resulted in significantly higher (*P*<0.05) incidences of simple hyperplasia and papillary or nodular hyperplasia than those in group 2C and a significant increase (*P*<0.01) in the average number of papillary or nodular hyperplastic lesions per 10-cm length of basement membrane. No significant difference was observed in the values between groups 2A and 2C. Groups of rats given PB alone (group 3A) or basal diet (group 3C) had normal bladder epithelium.

In this experiment, 6 rats in group 1B and 7 rats in group 2A had both liver and bladder neoplastic lesions. In the urinary bladder, neither calculi nor parasites were observed in any rat, and neoplasms other than in the liver or bladder were not observed.

DISCUSSION

In the present 36-week experiment, the total doses of 2-FAA (group 1C) or BBN alone (group 2C) were subcarcinogenic for liver and bladder. Following 2-FAA treatment, PB enhanced the induction of hyperplastic liver nodules and induced hepatocellular carcinomas, but did not affect the bladder mucosa. PB also induced hyperplastic liver nodules after BBN treatment, but it did not enhance bladder neoplasia induction. Conversely, after BBN treatment, SS enhanced the induction of bladder hyperplastic lesions but did not affect the liver. SS also induced bladder hyperplasia after 2-FAA treatment but did not enhance liver neoplasia induction. These data indicate that 2-FAA and BBN act as initiators for the liver and bladder—2-FAA with greater activity for the liver and BBN with greater activity for the bladder. BBN, in contrast to 2-FAA, appears to have only initiating activity for the liver similar to that of other nonhepatocarcinogens (*4*, *5*), but it is not a complete carcinogen for the liver.

SS promoted the induction of bladder neoplastic lesions in rats after initiation with 2-FAA (group 1B) and BBN (group 2B), with similar results to those after administration of other bladder carcinogens (*8*, *9*). However, the described effects of PB on the liver after 2-FAA treatment (group 1A, table 1) and of SS on the bladder after BBN treatment (group 2B, table 2) have already been reported previously (*3*, *10*). Since hyperplastic nodules and papillary or nodular hyperplasias are thought to be preneoplastic lesions of the hepatocellular and bladder carcinomas, respectively, if the experimental period is extended over 36 weeks, similar results might be obtained to those of Tatematsu et al. (*21*) and Ito et al. (*22*).

The results of the present experiment indicate that PB and SS act as promoters specific for liver and bladder, respectively. These results are consistent with other results showing that PB did not enhance the appearance of 7,12-dimethylbenz[*a*]anthracene-induced skin tumors (*23*) or dimethylnitrosamine-induced lung tumors (*6*), and that PB increased the incidence of spontaneous liver tumors but had no effect on the incidences of other spontaneous tumors (*24*). Also, SS did not enhance the appearance of benzo[*a*]pyrene-induced forestomach tumors (*25*). In contrast, promoters of skin carcinogenesis in mice, including croton oil (*1*), phorbol (*2*), and 12-*O*-tetradecanoylphorbol 13-acetate (*2*), have been reported to have promoting effects on carcinogenesis of various organs, such as breast (*11*), liver and lung (*7*), forestomach (*15*), and glandular stomach (*16*). Additional studies are needed to determine the mechanisms involved for the organ specificity of tumor promoters.

Serologic Analysis of Nitrosourea-Induced Rat Gliomas[1,2,3,4]

Michael Pfreundschuh,[5] **Humberto Cravioto,**[6,7] **Gerald Hochwald,**[8] *and* **Joseph Ransohoff**[9,10]

ABSTRACT—Inbred CDF rats (cesarean-delivered F344 rats) were immunized with either a nitrosourea-induced glioma EA-285 or its subline EA-285A and both with and without *Corynebacterium parvum*. A humoral immune response in syngeneic rats to the immunizing tumor was demonstrated with micromodifications of different rosette assays (immune adherence assay, protein-A assay, and anti-C3-mixed hemadsorption assay). Extensive absorption studies of two immune sera with the highest reactivity revealed two glioma-specific antigens (or two components of one antigen) on the cell surface of the cloned tumor subline. One antigen was present only on the cell surface of the subline of the glioma used for both immunization and absorption analyses. The other antigen appeared on the cell surface of both the cloned subline EA-285A and the parental cell line EA-285. These preliminary studies showed that CDF rats immunized against a syngeneic glioma mounted a humoral immune response that appeared to be individually tumor-specific.—JNCI 1982; 68:501–505.

Nitrosourea compounds are highly selective carcinogens for the nervous systems of rats (*1–4*). Nitrosourea-induced neurogenic tumors grow well in tissue culture, and the cultured tumor cells grow intracerebrally or sc when transplanted to syngeneic hosts (*5–11*). The immunogenicity of these tumors has been observed in vivo (*12, 13*) and by in vitro procedures (*14–17*). In all of these studies, however, the specificity of the immune response was not extensively or sufficiently tested by absorption studies with normal or neoplastic allogeneic and syngeneic cell lines (*17*). The aim of this work was a study of the specific humoral immune responses of syngeneic rats to an *N*-methyl-*N*-nitrosourea-induced glioma from the inbred, cesarean-delivered F344 rat (CDF rat). All CDF glioma cell lines studied here were induced by nitrosourea compounds and were kept in our laboratory. The sensitive C3MHA assay was used, because it allows serum-saving dilutions for extensive absorption analysis (*18*). For comparison, the IA assay and the PA assay were also used (*18*).

MATERIALS AND METHODS

Tumor cell line.—The glioma cell line EA-285 was a cerebral astrocytoma induced after eight monthly iv injections of 20 mg *N*-methyl-*N*-nitrosourea/kg body weight (total dose, 45 mg) into a CDF male rat from the Charles River Breeding Laboratories, Wilmington, Mass. The in vivo and in vitro morphology and some of the biologic characteristics of this tumor have been described in detail (*4, 9, 13*). EA-285A is a subline derived from this tumor that, in contrast to the uncloned parent tumor, kept its astrocytoma-like morphology even after long-term tissue culture (*13*). The cell lines were examined regularly for bacterial, fungal, and mycoplasma infections. If contaminated, the cultures were discarded. The cell lines used for absorption studies (*see* table 2) have been previously described (*17–20*). The allogeneic rat sarcomas SP 72, SP 73, and SP 76 were from Dr. S. Matzku, the German Cancer Research Center, Heidelberg.

Immunization.—Syngeneic CDF rats were immunized by injections of either irradiated (10^4 rad) trocar tumor pieces or 10^6 irradiated (5×10^3 rad) cultured cells (Gammator M. Radiation Machinery Corp., Parsippany, N.J.). In some rats the tumor cells were mixed with *Corynebacterium parvum* (Formalin-killed organisms, active strain 6434; Burroughs-Wellcome Co., Research Triangle Park, N.C.). The two immune sera with the highest tumor antibody titer were 230 and 352. Serum 230 was obtained from a male CDF rat given an sc injection in the right and left limbs of 1×10^5 EA-285A cultured cells together with 0.007 mg of *C. parvum.* Serum 352 was obtained from a male CDF rat immunized with irradiated trocar pieces of EA-285 tumor. The trocar used for sc transplant was an 18-gauge, 3.5-cm-long needle fitted with a plunger and filled with irradiated tumor. Three sc injections and one ip injection of trocar tumor pieces at weekly intervals were followed 2 weeks later by an sc challenge of 10^5 cultured EA-285 cells. Allogeneic serum 266 was obtained after two sc injections of a WF rat with 10^7 CDF glioma EA-285A cultured cells. Serum 255 was taken from a normal male nonimmunized CDF rat.

IA assay.—Indicator cells were huRBC stored in Alsever's solution up to 4 weeks. The huRBC were washed three times in VBM at 4°C and resuspended to a 0.2% (vol/vol) solution

in VBM. The complement source, 7.5-μl aliquots of 1:50 dilutions of guinea pig serum in a 0.2% (vol/vol) suspension of huRBC in VBM, was added to each well and incubated at 37°C for 30 minutes. The guinea pig serum was screened for high complement activity and low heteroantibody reactivity for rat cells as previously described (*18*). The plates were then washed once in VBM and scored.

C3HMA assay.—For preparation of the C3MHA assay indicator cells, SRBC, which were stored in Alsever's solution up to 2 weeks, were washed three times in PBS and resuspended in a 20% (vol/vol) concentration. Equal volumes of this SRBC solution and heat-inactivated rabbit anti-SRBC serum (Cappel Laboratories, Cochranville, Pa.) at a subagglutinating concentration of 1:200 were incubated for 30 minutes at room temperature. The antibody-coated SRBC (EA) were washed once in PBS and once in VBM and resuspended at 10% (vol/vol) in VBM. To obtain EAC14 cells, we incubated this EA solution on ice with prescreened guinea pig serum at a final concentration of 1:40 for 7.5 minutes, after which we washed the solution twice and resuspended it at 2% (vol/vol) in VBM. Equal volumes of this EAC14 solution and guinea pig complement components C2 and C3 (Cordis Laboratories, Miami, Fla.) at 200 U/ml in VBM were mixed and incubated for 30 minutes at 30°C to produce EAC423. The cells were washed twice in VBM, resuspended at 0.5% in VBM, and incubated with an equal volume of a subagglutinating concentration (1:80) of goat anti-guinea pig C3 (Cappel Laboratories) at room temperature for 1 hour. The EAC423 anti-C3 cells were washed twice and resuspended at 0.5% (vol/vol) in VBM. Preparation of target cells and serum incubation were performed as described for the other assays. After serum incubation, the plates were washed three times in VBM. Then 10 μl of prescreened guinea pig serum was added as a source of complement at a concentration of 1:50 in VBM and incubated for 10 minutes at 37°C. The wells were washed three times in VBM, and 7.5 μl of the 0.5% (vol/vol) EAC423 anti-C3 indicator cell solution in VBM was added to each well. After 30 minutes at room temperature, the wells were washed once in VBM and scored

PA assay.—The huRBC were washed twice in VBM and once in saline. To 1 volume of a 10% (vol/vol) huRBC solution in saline, a 1/10 volume of PA (1 mg/ml; Pharmacia Fine Chemicals, Freiburg, Federal Republic of Germany) was added slowly and mixed. One volume of chromium chloride ($CrCl_3$–$6H_2O$; E. Merck A.G., Darmstadt, Federal Republic of Germany), 0.02% (wt/vol) in saline, was added dropwise while the mixture was being shaken. The mixture was incubated for 5 minutes at room temperature. The reaction was stopped by addition of excess VBM, and the PA-coated huRBC were washed twice and resuspended at 10% (vol/vol) in VBM. After serum incubation, plates were washed three times with VBM, and 7.5 μl of 0.2% (vol/vol) PA indicator cell suspension in VBM was added to each well. The plates were incubated for 45 minutes at room temperature, washed once with VBM, and scored.

Evaluation.—All tests were scored with the aid of an inverted microscope. Individual cells were scored positive when 50% or more of the cell perimeter was covered by indicator cells. In each case, at least three red blood cells were attached to a positive cell. Target cells showed a clear-cut positive or negative phenomenon. On the rare occasion when only one or two indicator cells were attached to a target cell, the test was scored as negative. The serum titer was read as the highest serum dilution to give at least 10% positive target cells in the respective well. For a test to be valid, control wells that had been incubated with VBM alone had to have less than 1% positive cells ("no background").

Background reactivity.—When seen, background reactivity is probably due to heteroantibody. As shown previously (*18*), background reactivity can be abolished by shortening the complementation time, probably because attachment of heteroantibody in the guinea pig serum to the surface of the target cells takes more time than complementation. This modification proved to be more consistent than preabsorption of guinea pig serum with rat target cells, which often led to variable reduction of complement activity. When the assay protocol was strictly adhered to, the modification of the serologic assays for microtiter plates #3034 (instead of #3040) did not affect sensitivity and reproducibility. Plates must not stand too long; otherwise, the wells may dry out. Plates must also be thoroughly washed.

RESULTS

The IA assay reactivity of different sera against EA-285A is shown in text-figure 1. The allogeneic serum had the highest reactivity at a titer of 1:32. The immune serum 352 had an IA assay titer of 1:8. In this experiment serum 355, a control serum from a non-tumor-bearing CDF rat, had no detectable reactivity against EA-285A. Text-figure 2 shows that the reactivity of serum 230 was highest in the C3MHA assay with a titer of 1:32. Reactivity of serum 230 as detected by PA and IA assays was lower, 1:8 and 1:16, respectively. Serum 352 showed a pattern similar to that of serum 230. The maximal serum reactivity obtained by the three assays is shown in table 1. The highest reactivity was obtained with allogeneic immune serum 266. In the C3MHA assay, sera 230 and 352 showed the highest reactivity (1:128) and were used in absorption studies (*see* below). Serum 355 from

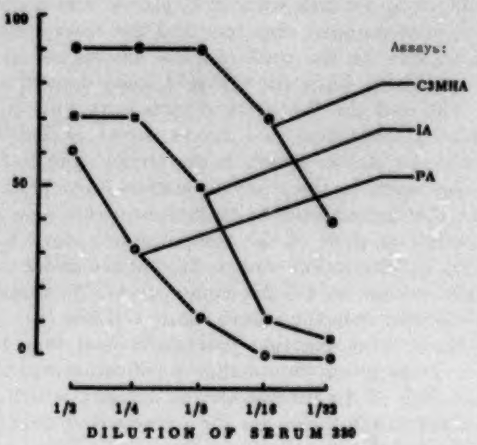
451	CDF	*C. parvum*	1:2[a]	0	1:4[a]
455	CDF	*C. parvum*	1:2[a]	0	1:4[a]

[a] Titers seen in these sera were nonspecific and were absorbed with EA-285A tumor cells as well as with CDF skin fibroblasts.

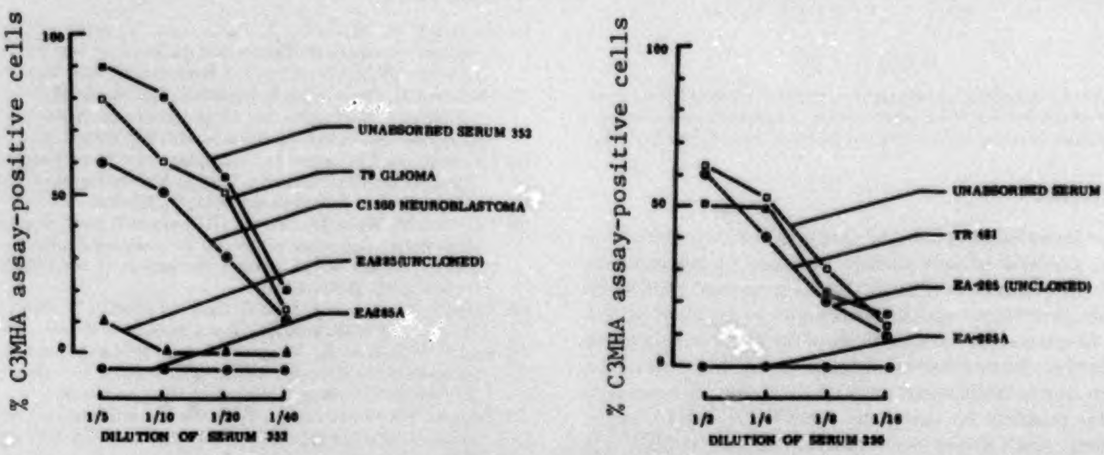
a normal male rat, similar to sera 451 and 455 (obtained from rats immunized with *C. parvum* only), showed no reactivity in the PA assay, a weak reactivity of 1:2 to 1:4 in the IA assay, and a reactivity of 1:4 to 1:8 in the C3MHA assay. However, this reactivity did not appear tumor-specific since it was absorbed by normal cultured CDF skin. The assay that gave the highest titer was the C3MHA assay. This assay was chosen to analyze the specificity of the anti-EA-285A reactivity because it allowed extensive absorptions with the use of diluted sera. These antisera were absorbed with a wide spectrum of syngeneic, allogeneic, and heterologous benign and malignant cells. Text-figure 3 illustrates individual absorption tests of serum 230 and serum 352. Table 2 summarizes the results of absorption studies performed with these sera. The antigen detected by serum 230 was restricted to syngeneic EA-285A glioma cells. Other cell types, including other syngeneic nitrosourea-induced CDF tumors of the nervous system and a panel of normal CDF tissue and fetal rat cells, did not absorb reactivity of serum 230. Serum 352 showed a similar absorption pattern as did serum 230. However, the C3MHA assay reactivity of serum 352 to EA-285A cells was also absorbed by the parental cell line EA-285.



TEXT-FIGURE 2.—Reactivity of serum 230 against syngeneic glioma EA-285A as detected by C3MHA, IA, and PA assays.

Quantitative absorption analysis of the antigen detected by serum 352.—Quantitative absorption tests were performed with the two cell lines expressing the antigen detected by serum 352. As measured by absorption capacity per cell, the original cell line EA-285 as compared to the cloned cell line EA-285A expressed one-third of this antigen on the cell surface (text-fig. 4).

Stability of antigen expression by cultured rat glioma cells.—Late in vitro passages of tumor cell lines EA-285 and EA-285A (147–215) were tested for the presence of the antigen detected by serum 230 or 352. In general, only minimal fluctuations (5–10% of early passages) in the strength of this syngeneic reaction and antibody titer could be detected. The specificity of the reactions, as determined by absorption analysis, remained constant, despite the late in vitro passage number.



TEXT-FIGURE 3.—Individual absorption tests of serum 352 (*left*) and serum 230 (*right*) C3MHA assay reactivity. Serum 230 was absorbed with the immunizing cell line EA-285A only, whereas serum 352 was also absorbed with the parental cell line EA-285. TR 481 is a malignant neuroma cell line (*13*).

DISCUSSION

To our knowledge this study contains the most extensive serologic analysis of cell surface antigens of nitrosourea-induced rat gliomas. Although there are several reports on the existence of tumor-specific antibodies to rat gliomas (*14, 15, 17*), an analysis of the specificity of the observed reactions was limited in the number of antigens tested. This limitation was often due to insufficient amounts of serum. We can now avoid this problem by using the modified C3MHA assay. The present study shows two important results: 1) CDF rats immunized against a syngeneic nitrosourea-induced glioma are able to mount a humoral immune response against this tumor, which seems to be individually tumor-specific [class I antigen (*20*)]. 2) Immunization with the in vitro cultured cells of the subline EA-285A gives rise to an antibody that detects an antigen present only in the subline; in contrast, immunization with the in vivo transplanted subline of the glioma induces in the syngeneic rat the production of an antibody that reacts with an antigen present in both the EA-285 tumor cell line and in the EA-285A cloned subline. The quantitative absorption analysis shows that this antigen is present in the subline at a concentration threefold greater than that found in the parental line EA-285. It is not clear whether the antigens detected by sera 230 and 352 are different antigens or different components of the same antigen. It is also uncertain whether or not the antigen present only in the cloned cell line and detected by serum 230 represents a new antigen that developed in vitro after cloning.

The addition of *C. parvum* to enhance the response to the tumor may result in the formation of antibodies to minor components and contribute to the production of the tumor-specific antibody in serum 230. The injection of the same number of tumor cells without *C. parvum* does not result in a consistent immune response, and the reactivities of the resulting sera are too weak to allow absorption analysis of their specificity. Since the C3MHA assay detects both IgG and IgM and the PA assay detects only IgG, it can be speculated that these two assays detect antibodies with different specificities present in one serum. A similar conclusion was made in the study of human astrocytomas (*20*). Again, the limited amount of immune serum available did not permit analysis of the comparatively weak PA assay reaction by absorption studies. Studies are under way with another subline of EA-285 tumor (EA-528) that is more immunogenic than the parent tumor cell line (*21*). The use of different immunization procedures that may result in higher titered serum should allow purification and biochemical analysis of the glioma-specific antigen, which may be important in the future for the treatment of animals with transplanted tumors.

Development and Biologic Properties of Malignant Cell Sublines and Clones of a Spontaneously Metastasizing Rat Mammary Adenocarcinoma[1,2,3]

Anthony Neri,[4,5] Dan Welch,[6] Takanori Kawaguchi,[6,7] *and* Garth L. Nicolson[6,8]

ABSTRACT—With the use of the rat 13762 mammary adenocarcinoma tumor, an animal model for spontaneous mammary tumor metastasis was developed. The parental tumor implanted sc into the mammary fat pads of female Fischer 344 rats metastasized at low frequency to lymph nodes and lung and did not metastasize to other organs. Oophorectomy did not modify the metastatic properties of the parental 13762 tumor. Cell lines were adapted to tissue culture from lymph node or lung metastases, and these were compared to parental tumor transplants in spontaneous metastasis assays. Only the cell lines established from metastases were spontaneously metastatic within 23 days after sc implantation, indicating that tumor cell populations from metastases are more metastatic than are cells from the parental tumor. Several individual parental tumor-derived and lung metastasis-derived clones were compared for spontaneous metastatic potentials, cell culture morphologies, histologic structures at primary implant and secondary metastatic sites, and growth characteristics in vivo and in vitro. There was no correlation between any of these tumor and cellular properties and metastatic potential. The parental mammary tumor-derived, lymph node metastasis-derived, and lung metastasis-derived cell lines and clones with differing spontaneous metastatic properties should prove useful in studies on the roles of tumor cell and host properties in lymphatic and blood-borne metastasis.—JNCI 1982: 68: 507–517.

Tumor metastasis is probably the most urgent problem in the management of cancer, because primary tumors can in most cases be treated effectively by a combination of treatments usually involving surgery, chemotherapy, and radiotherapy. However, metastatic tumor cells have often spread to other sites before they are detected and treated (*1, 2*). Therefore, efforts to elucidate and better understand the events and processes involved in metastasis should lead to improved and more effective means of cancer control.

For malignant cells to spread from the primary sites to near and distant secondary sites, the tumor cells must invade surrounding normal tissues, penetrate blood and/or lymphatic vessels, dislodge from the primary tumor mass, disseminate to distant sites, arrest in the lymph nodes or microvasculature of distant organs, and finally invade the parenchyma and stroma at these sites to survive and grow into gross metastatic colonies (*3–5*). Metastasis is a complex biologic process, and its final outcome is influenced by both host factors and tumor cell properties (*5–7*). That this process is the end result of several highly selective sequential steps during which only a few calls eventually survive suggests that only a small fraction of cells in the primary tumor is capable of completing the entire sequence (*4–6*). Heterogeneity in metastatic potential within malignant cell populations has been found in several animal tumor model systems (*8, 9, 10–14*). In addition to heterogeneity in metastasis, evidence is increasing that single neoplasms can be comprised of subpopulations that vary in other characteristics such as in vivo and in vitro growth potential (*15, 16*), drug sensitivity (*15, 17–20*), immunogenicity (*21–23*), and radiosensitivity (*24, 25*). Therefore, it is not surprising that therapeutic measures taken against metastatic disease are often ineffective.

To better define tumor cell and host properties related to the metastatic process, one must have suitable animal tumor models that resemble human metastatic disease (*5, 26*). In addition, the experimental models should allow for the selection of malignant subpopulations with low and high metastatic potentials. Such animal metastatic models have been developed for certain histologic types of tumors, such as melanoma (*27–30*), fibrosarcoma (*10, 11*), carcinoma (*12, 31, 32*), lymphosarcoma (*33*), and sarcoma (*9, 34*). Although breast cancer metastasis is the leading cause of death in women 35–54 years old (*35*), suitable animal models for studying mammary tumor metastasis with the use of high and low metastatic cell sublines from the same parental tumor have not been available. We now report on the establishment of an animal tumor model for the experimental study of spontaneous metastasis of a rat mammary adenocarcinoma from mammary sites to distant secondary sites as well as biologic characterization in vivo and in vitro of cell lines and clones isolated from the parent tumor and metastases that exhibit different metastatic potentials.

MATERIALS AND METHODS

Animals.—Female Fischer 344/CRBL rats 6–9 weeks of age were used. They were fed a diet of Wayne Lab-Blox (Allied Mills, Inc., Chicago, Ill.) and tap water with a chlorine content of 0.35–0.80 ppm. All animals used for experimentation were healthy as determined by visual observations and by diagnostic laboratory tests performed by the Veterinary Laboratory Services (Irvine, Calif.) for viral, bacterial, fungal, and parasitic infections.

Mammary adenocarcinoma tumor line.—The mammary adenocarcinoma line 13762 was originally developed by Segaloff (*36*) by dietary administration of 7,12-dimethylbenz[*a*]anthracene. The tumor has since been maintained by in vivo sc serial passages in syngeneic female Fischer 344 rats and as frozen stocks in liquid nitrogen. The frozen form of the 13762NF solid tumor was obtained in 1977 from the Mason Research Institute, Worcester, Mass. Upon arrival, the frozen tumor specimen was thawed quickly in a 37°C water bath, washed three times with 10 ml AMEM (*37*) without antibiotics or serum. The tumor tissue was then transferred to a 35-mm plastic petri dish (Corning Glass Works, Corning, N.Y.) and cut into 2×3-mm pieces with the use of iridectomy scissors. Eight rats were lightly anesthetized with Metofane (methoxyflurane; Pitman-Moore, Inc., Washington Crossing, N.J.), and tumor pieces measuring 2–3 mm were individually implanted sc by surgical incision in the mammary fat pad. The incision was closed with wound clips. Tumor-bearing animals were observed and palpated twice weekly for primary tumor growth and possible metastases to inguinal and axillary lymph nodes. Animals suspected of having metastases were killed, the primary tumors were measured, and the pleural and visceral organs were examined with the aid of a dissecting microscope for the presence of tumor lesions. In all cases, secondary tumors were verified by histologic examination of paraffin-embedded samples prepared from tumor-involved tissues.

Oophorectomy.—Animals were oophorectomized to determine whether the growth and metastasis of the parental 13762 adenocarcinoma tumor were affected by ovarian hormones. The ovaries of 10 rats were surgically excised, and the animals were allowed to recover for 14 days. Following the recovery period each oophorectomized rat received an sc implant of 2×3-mm tissue from the parental tumor in the mammary fat pad. The source of tumor tissue fragments used for transplantation was a subcutaneous growth of the parental tumor. The fragments were derived from fleshy, peripheral areas of the tumor distant from any necrotic regions. Rats that did not have their ovaries removed but had received equivalent fragments of parental tumor tissue served as controls. After 40 days the animals were killed by anesthesia (Metofane), their primary tumors measured, and their organs examined with the aid of a dissecting microscope for the presence of surface tumor nodules.

In vivo growth and spontaneous metastasis of the parent tumor 13762 line.—Tumor tissue obtained from peripheral, nonnecrotic regions of the parental tumor was cut into 2×3-mm fragments and implanted sc into the mammary fat pads of recipient rats. The animals were killed by anesthesia (Metofane) at 23 and 40 days post tumor implantation. The implanted (subcutaneous primary) tumors were then measured, and the organs of all animals were examined with the aid of a dissecting microscope for surface tumor lesions.

Establishment of tissue culture cell lines and clones from the parental 13762 adenocarcinoma and its metastases.—Parental tumor tissue fragments were removed with the use of sterile forceps and a scalpel from peripheral, nonnecrotic regions of a single tumor measuring 4 cm in diameter after 40 days of subcutaneous growth. Four tissue fragments having a total wet weight of approximately 1.5 g were transferred to a sterile 35-mm plastic petri dish containing 5 ml of cold AMEM without antibiotics plus 10–20% heat-inactivated fetal bovine serum (Flow Laboratories, Inc., Inglewood, Calif.) (CM). The fragments were subjected to ten rinses (5 ml each) with cold CM. After the final rinse the medium was aspirated and the fragments were finely minced with sterile iridectomy scissors. After 5 ml CM was added to the minced tissue, the tissue was transferred with the use a widebore sterile pipette to a 15-ml sterile plastic conical centrifuge tube. The tube was placed in an ice bath, and the minced tissue was allowed to settle. The supernatant was decanted, and the settled tissue mince was washed three times with 10 ml each of cold CM. Finally, the minced tissue was resuspended in 10 ml of CM containing 1 mg crude collagenase/ml (100 U/mg, CLS III; Worthington Biochemical Corp., Freehold, N.J.). The tissue was distributed into ten 75-cm^2 tissue culture flasks (Corning Glass Works) containing 9 ml of CM with 1 mg collagenase/ml each and incubated at 37°C in a humid atmosphere of 95% air–5% CO_2. After 72 hours of incubation in the presence of collagenase, very few cells were found to be attached to the substratum; instead, most cells were found to be floating in the medium as single cells or loosely adhering cell aggregates. The medium containing the single cells and aggregates was collected from each culture and centrifuged at 180×*g* for 5 minutes. The cell pellets were resuspended in 10 ml of fresh CM and distributed into five 75-cm^2 culture flasks containing 9 ml of CM each. To facilitate attachment to the substratum, we left the cultures undisturbed for 5 days at 37°C. The cultures were then examined for cellular attachment and growth. When the cultures had reached approximately 50–60% confluence, they were detached with the use of 3 ml of prewarmed 0.25% trypsin (Difco Laboratories, Detroit, Mich.; 1:250) in DPBS-CMF (*38*). CM (10 ml) was then added to each flask to inhibit trypsin activity. Viable cell counts were determined with the use of 0.1% trypan blue in DPBS-CMF with a hemacytometer.

Metastatic tumor lesions from lungs and axillary lymph nodes were established in tissue culture. The source of metastases was the same animal whose primary parental tumor was established in tissue culture. An enlarged axillary lymph node measuring 8 mm in diameter was excised surgically and aseptically and placed in a 35-mm petri dish containing 5 ml of cold CM. The lungs of an animal possessing over 15 surface tumor nodules were removed and placed in a separate petri dish containing 5 ml of CM. Five surface tumor nodules were selected, dissected away from normal lung tissue, and transferred to another petri dish containing 5 ml of CM. Tissue cultures of the parent tumor and its lung metastases were subjected twice to single cell cloning procedures according to Neri and Nicolson (*39*).

In vitro analysis of growth rates and saturation densities.—Tumor cell clones derived from tissue culture of parental tumor and metastatic lung lesions were analyzed for differences in growth rates and saturation densities. For growth rate studies, established cultures of individual clones were detached with the use of 0.25% trypsin in DPBS-CMF, reseeded into 25-cm^2 flasks at an initial density of 4×10^3 viable cells/cm^2 in 5 ml of CM, and incubated for 6 days without medium change. Cell counts were obtained every 24 hours on triplicate cultures with the use of a hemacytometer. The conditions used for the determination of saturation densities were identical to those used for the growth rate analysis except for the addition of fresh CM at 96 hours during log phase growth and thereafter every 24 hours until each clonal culture reached stationary growth phase.

In vivo biologic assays.—Individual clones derived from the parental tumor and from lung metastases were analyzed for their extent of growth and capacity to metastasize spontaneously from subcutaneous sites. Tissue cultures of tumor cell clones that were 80–90% confluent were detached with the use of 0.25% trypsin in DPBS-CMF and washed twice with 15 ml of cold AMEM, and cell numbers and viabilities were determined. Cell suspensions over 90% viable were used for all injections. Animals were anesthetized lightly with Metofane and given injections sc with the use of a 25-gauge needle on a 1-ml syringe in the mammary fat pad with 1×10^6 viable cells in 0.5 ml of AMEM. All animals were killed with Metofane 23 days post tumor cell injection. Tumors growing at the site of injection were measured, organs were removed and rinsed in DPBS, and each organ was examined with the aid of a dissecting microscope for tumor involvement. Tissue samples from primary tumor sites and metastatic sites were prepared for histology.

Histology.—Tissues were prepared for histology by fixation in Bouin's solution (24 hr) followed by dehydration, paraffin embedding, and sectioning. Sections 4–6 μm thick were stained with H & E.

Mycoplasma testing—Tissue cultures of all cell lines and clones were routinely screened with the use of Hoechst 33258 stain (Calbiochem-Behring Corp., Los Angeles, Calif.) for the presence of mycoplasma contamination prior to animal injections by the procedures of Chen (*40*).

RESULTS

Growth and Spontaneous Metastasis of the Parental Tumor in Oophorectomized Rats

No significant differences in the extent of growth or spontaneous metastases of the parental mammary adenocarcinoma tumors were observed between oophorectomized and control animals. Forty days after tumor implantation the oophorectomized group (10 rats) and the control animals (15 rats) had subcutaneous tumors measuring 44.6±8.4 and 45.6±7.2 mm (average diameters ± SD), respectively. Gross observations of pleural and visceral organs for metastases also revealed no apparent differences. Of the oophorectomized animals, 20% (2/10) had surface pulmonary tumor nodules (median=11; range=1, 112). In the control group that had not undergone oophorectomy, 5 of 15 animals had visible surface pulmonary tumor nodules (median=5; range=1, 72). Lymph node metastases were found in 60% (6/10) and 53% (8/15) of the oophorectomized and control animals, respectively; other organs in both groups were negative.

In Vivo Biologic Characteristics of the Parental Tumor

The growth and metastatic profiles of the parental mammary adenocarcinomas in syngeneic female Fischer 344 rats were examined (table 1). Animals receiving parental tumor tissue fragments (2×3 mm) sc were killed 23 days later and examined. Metastases were not detectable, including metastases in lymph nodes or pleural and visceral organs. The subcutaneous tumors at this time had mean diameters of 29±4.8 mm, grew as scirrous-like masses that did not erupt through the skin, and exhibited only slight central necrosis with very little fluid accumulation. In contrast, among the 56 animals that were killed 40 days after sc tumor implantation, 31 rats had metastases to the lymph node (inguinal, axillary, lumbar, and/or mesenteric nodes) and 23 had lung metastases (median number of lung surface tumor foci=5; range=1, 65). All other organs examined, such as liver, spleen, kidneys, and ovaries, were negative for visible tumor metastases. The subcutaneous tumors had mean diameters of 45.90±9.3 mm. At that stage, the tumors had erupted through the overlying skin and exhibited centers of necrosis.

To minimize the possibility that subclinical micrometastases were present deep within the organs and therefore not detected by visual observations, we excised and minced the organs from randomly selected animals with no visual indication of tumor involvement. Portions of the tissue minces representing each organ (i.e., lungs, liver, spleen, kidneys, ovaries, and regional and distant lymph nodes) were implanted sc in mammary fat pads of groups of rats. The animals were observed for tumor growth over 3 months, but no tumors developed in these animals within that period.

Established Cell Lines and Clones of 13762 Adenocarcinoma

Primary cultures established from the parental tumor were comprised of cells with different morphologies. Morphologic heterogeneity ranged from fibroblastic to epithe-

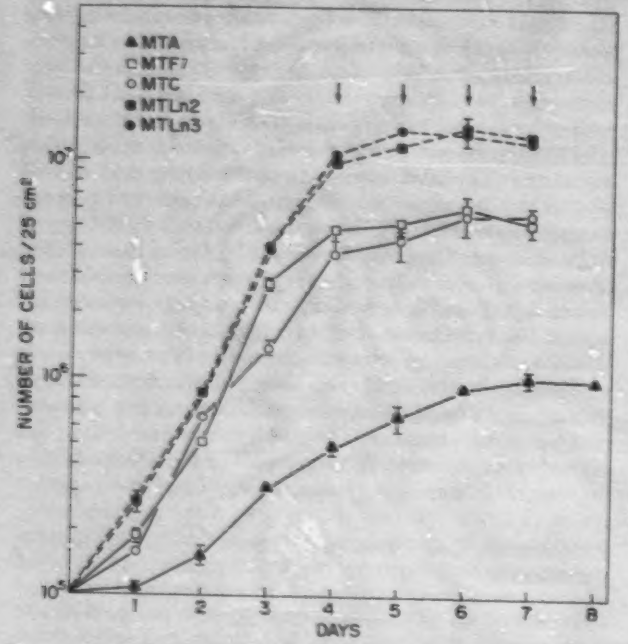
lial, and these morphologic types were often separated by distinct boundaries. Parallel primary cultures not subjected to cloning were allowed to reach confluence and were subcultured continuously for 6–7 weeks, which resulted in cell lines that were morphologically uniform and exhibited only fibroblastic morphologies. That these cultures represented overgrowth by normal host fibroblasts was suggested by their inability to produce subcutaneous tumors over 4 months in syngeneic rats (5 rats/group; injection, up to 10×10^6 viable cells/rat). We concluded that the cloning of parental tumor lines must be initiated as early as possible to prevent subsequent overgrowth of tumor cells by normal fibroblasts.

Primary cultures of parental tumor exhibiting a large degree of morphologic heterogeneity were subcultured and immediately subjected to cloning procedures. Selected clonal variants possessed mainly fibroblastic or epithelial-like morphologies (fig. 1). Cell clones derived from cultures of lung metastases were not as morphologically heterogeneous as were clones obtained from the parental primary tumor (fig. 2).



TEXT-FIGURE 1.—*In vitro* growth rates of mammary tumor clones. Cultures were seeded initially at 10^5 cells/25-cm² flask and refed at the indicated (*arrows*) times.

In Vitro Growth Rates and Saturation Densities of Adenocarcinoma Clones

In vitro growth studies of the selected clones revealed differences in growth rates and saturation densities (text-fig. 1). Clones derived from metastatic lung lesions (MTLn2 and MTLn3) had generation times of 13.5 hours and final saturation densities of 6×10^5 cell/cm², while clones obtained from the parental tumor (MTC and MTF7) possessed mean generation times of approximately 16.5 hours and saturation densities of $2.2–2.4\times10^5$ cells/cm². Clone MTA differed dramatically from the other clones; it exhibited a generation time of approximately 28.6 hours and a final saturation density of 4×10^4 cells/cm² (text-fig. 1).

In Vivo Biologic Characteristics of Adenocarcinoma Cell Lines and Clones

To determine whether the tumor cells from secondary metastatic lesions represented cells with enhanced metastatic potentials, we injected sc the uncloned tumor cell cultures established from axillary lymph nodes and lung metastases (1×10^6 viable cells in the mammary fat pad). The animals were killed 23 days later and examined for gross metastases. A striking difference in the extent of subcutaneous growth and potential to metastasize was found between lung metastasis or lymph node-derived tumor cell lines and cells from the parental tumor (table 2). All animals receiving injections sc in the mammary fat pads of metastasis-derived tumor cells developed both lymph node (inguinal, axillary, and lumbar) and lung metastases, whereas animals inplanted with parental tumor tissue (2×3 mm, sc in the mammary fat pads) showed no detectable metastases in organs or lymph nodes. The difference in the metastatic potentials of metastasis-derived tumor cells compared to the parental tumor-derived cells was not simply due to in vitro cultivation, because direct sc transfer of lymph node and lung metastatic lesions (5 rats with lung and 5 rats with axillary lymph node metastases) resulted in patterns of metastasis similar to those found with tissue culture-adapted cells (data not shown). These results indicated that in this system tumor cell populations from secondary lesions pos-

[b] No. of animals with metastases/total No. of animals given tumor implants.

sessed enhanced metastatic potentials when compared to those found in cells from the parental tumor.

Evidence that the parental tumor was comprised of subpopulations of tumor cells that varied in their capacity to metastasize was revealed by in vitro cloning followed by the analysis of the clones for their in vivo biologic behaviors. Tumor cell clones from primary cultures of the parental tumor varied widely in their ability to grow at the site of inoculation and produce distant metastases after 23 days of subcutaneous growth (table 3). This end point was chosen because some of the clones killed their host before 40 days. Tumor clone MTA displayed the highest metastatic potential with approximately 94% of the animals exhibiting pulmonary metastases, although the sizes of the primary tumors at the subcutaneous sites of injection were comparatively small. In contrast, tumor clone MTF7 produced significantly larger tumors at the injection site; but it was intermediate in metastatic potential, producing pulmonary metastases in 52% of the animals. Clone MTC gave rise to primary implanted tumors of intermediate size and demonstrated the lowest metastatic potential of the clones examined with only 10% of the animals given injections developing pulmonary metastases (median No.=2; range=1, 6). Clones obtained from the parental tumor (MTA, MTF7, and MTC) did not form detectable extrapulmonary metastases in any of the experiments, as confirmed by gross observations and direct subcutaneous transfer of randomly selected organ and lymph node tissues.

The lung metastasis-derived clones MTLn2 and MTLn3 were also examined for their ability to produce spontaneous metastases after 23 days of in vivo subcutaneous growth (table 3). Clone MTLn3 produced lung metastases in 76% of the animals examined and lymph node metastases (axillary, inguinal, and lumbar) in 21% of the animals examined. Although clone MTLn2 originated from metastatic lung lesions, it had a low metastatic potential, producing pulmonary metastases in only 11% of the animals and no apparent lymph node involvement. These results indicate that both the parental tumor and its metastases are composed of subpopulations of tumor cells that vary not only in their growth properties but also in their metastatic potentials.

Histology

The tumors formed from subcutaneous mammary pad implants of parental tumor and cloned cell lines are shown histologically in figure 3. The parental 13762NF tumor grew in small, dense cell clusters or strands of varying morphologic types, sizes, and staining characteristics, but common to most cells were a slightly basophilic cytoplasm and high mitotic index. Within the tumor mass only small amounts of fibrous tissue could be found, and very little overall cellular organization was seen except for some luminal formation. The parental tumor was classified histologically as an undifferentiated adenocarcinoma. Clones derived from the parental tumor or lung metastases varied histologically from poorly differentiated adenocarcinoma with definite luminal formation (i.e., MTLn2) to scirrous-like, well-vascularized undifferentiated carcinoma (i.e., clones MTC and MTF7). Clone MTA was quite different from the other clones and was similar in structure to a giant cell sarcoma of unknown origin (fig. 3). Metastases formed by the sc implantation of the tumor cell clones also reflected the structural heterogeneity of the parental tumor (fig. 4). Lung metastases were more uniform in histologic structure, often representing the morphologies of minor subpopulations present in the subcutaneous tumors (i.e., clone MTA) (fig. 4). In many cases host lymphocytes, granulocytes, or polymorphonuclear cells were present in the metastatic lesions (fig. 4).

DISCUSSION

The results of these studies and those of others show that parental tumors and their metastases are composed of subpopulations of tumor cells that differ in certain in vitro and in vivo biologic characteristics. We have shown that variant cell subpopulations (clones) can be obtained from cultures of both the parental tumor and its lung metastases, and this heterogeneity was confirmed when these clones were assayed

for in vivo and in vitro growth properties, in vitro saturation densities, in vitro morphologies, and in vivo histologic appearance. Although the several clones that were tested varied in their in vitro growth rates and saturation densities, these parameters did not correlate with their metastatic potentials. Two parental tumor clones, MTC and MTF7, had similar growth rates and saturation densities in vitro but differed significantly in their abilities to metastasize. The same was true for clones MTLn2 and MTLn3 that were selected from lung metastases. Both of these clones exhibited similar growth rates and saturation densities in vitro, but they differed in their ability to form distant metastases. Parental clone MTA, which had the lowest growth rate and saturation density of all clones in vitro, displayed the highest metastatic potential. In contrast, lung metastasis-derived clone MTLn2, which demonstrated a high growth rate and saturation density in vitro, had a relatively low metastatic potential.

The extent of subcutaneous tumor growth at the site of inoculation was unique for each clone and did not correlate with their metastatic potentials. That the subcutaneous tumor size and growth rate of a tumor are poor indicators of the capacity of the tumor to metastasize successfully has also been reported in other animal tumor systems (*8–16, 41, 42*) and in human breast cancer (*1, 2*). In light of the findings presented here and elsewhere (*9–15*), that single neoplasms contain heterogeneous subpopulations of tumor cells with differing metastatic potentials, it is not surprising that the overall size or growth rate of a tumor may not reflect its metastatic potential. More likely, the metastatic potential of a tumor is determined by the relative frequency and/or emergence of highly malignant subpopulations (*43*) that possess characteristics allowing them to metastasize successfully. The direct in vitro isolation of metastatic clones from the parent tumor indicates that these metastatic subpopulations preexisted and were not formed by adaptive processes (*44, 45*). Furthermore, that the lung metastasis-derived clones reflect an organ adaptive process is unlikely, since the two clones examined here differed significantly in their capacity to form pulmonary metastases and the derivation of clones from lung metastases did not involve repeated in vivo cycling of metastatic variants with the use of the lungs as a selective environment. The presence of a poorly metastatic subpopulation of tumor cells within lung metastatic lesions suggests that metastases are comprised of tumor cell subpopulations that vary in their ability to form subsequent metastases. A similar conclusion was reported for metastatic subpopulations and clones obtained from a fibrosarcoma (*44*).

Of the animal models that exist for studying mammary tumor metastasis, most are mouse tumor models that exhibit few similarities to human breast cancer (*46*). Carcinomas from mice generally grow rapidly, and most express high levels of mammary tumor virus and rarely metastasize; when metastasis occurs, it is usually hematogenous (*46*). In contrast, rat mammary carcinomas show many similarities to human breast cancer, such as tumor histologic structure, mode of metastasis (*47*), immunogenicities and sensitivies to immunotherapy (*48*), and responsiveness to hormone (*36, 49, 50*) or steroid manipulations (*51, 52*).

The rat mammary adenocarcinoma used in these studies was induced chemically in female Fischer 344 rats. The clones obtained from this tumor exhibit significant differences in their histologic appearances, ranging from sarcoma-like to poorly differentiated ductal structures. The apparent histologic variations that we found are consistent with those reported by others who observed that chemically induced rat mammary tumors can display histologic heterogeneity between tumors and within the same tumor (*53, 54*). Although one can argue that the heterogeneous nature of the 13762 adenocarcinoma is due to its long-term existence as a transplanted tumor, such phenotypic diversity has also been noted in tumors of recent origin (*55*). We attempted to obtain not only variant cell subpopulations that differed in their metastatic capacities but also subpopulations that were histologically similar to human mammary carcinomas. We do not imply here that we have obtained even a fraction of the subpopulations that may exist within a mammary tumor; however, the tumor clones described here serve to illustrate the heterogeneous nature of this neoplasm in respect to growth, histology, and metastasis. In addition, the tumors formed by these cell clones display varying degrees of host lymphoid cell infiltration both at the subcutaneous sites and their metastases. The relationship between host cell infiltration and biologic or metastatic behavior of these tumors is at present unclear and will require further studies.

Among the clones tested, only MTLn3 exhibited extensive and reproducible lymph node metastasis. This clone is of special interest since human mammary adenocarcinomas frequently metastasize to regional lymph nodes (*2*). The possibility that a difference in the mode of metastasis was imposed at the injection site can be ruled out since all clones were introduced at the same subcutaneous site in the mammary fat pad. Although lymph nodes were examined histologically for the presence of occult metastases, we cannot rule out the possibility that tumor cells from the other clones did in fact reach lymph nodes, but in such small numbers that they were either destroyed by host immunocytes or were unable to grow.

The process of tumor metastasis is biologically complex, and its study requires appropriate experimental models (*3, 5, 26, 32*). The model that we have established for mammary tumor metastasis has already shown its usefulness in studies on the differences in cell surface glycoproteins between cells of diverse metastatic potential (*39, 56*) and heterogeneity in therapeutic response to ionizing radiation (Welch D, Milas L, Nicolson GL: In preparation) and hyperthermia (*57*). By the examination and comparison of cell clones of low and high metastatic potentials for their biologic, biochemical, and other properties, it is hoped that unique characteristics possessed by metastatic populations will be better defined.

E) Clone MTF7 lung metastasis. Some cells in alveolar lumen resemble cells found in the subcutaneous tumor. These lesions are characterized by extensive infiltration by lymphocytes, monocytes, and granulocytes. F) Clone MTLn2 lung metastasis. Tumor cells in the alveolar septum have retained much of the nodular organization seen in subcutaneous tumors. Tumors were also characterized by large numbers of lymphocytes and granulocytes and a few polymorphonuclear cells. H & E. *Bars*=50 μm. × 160

Temperature Gradients and Local Perfusion in a Mammary Carcinoma[1,2]

Pietro M. Gullino,[3,4] **Rakesh K. Jain,**[5] *and* **Flora H. Grantham**[3]

ABSTRACT—Temperature gradients of mammary tumors in randombred Sprague-Dawley rats under normothermia, hypothermia, and hyperthermia were determined, and their experimental modifications were utilized to assess differences in perfusion rates within the neoplastic tissue. Normothermic tumors showed a circadian rhythm with zenith at midnight and nadir at midday. Differences between highest and lowest temperatures recorded during the 24-hour period reached up to 3°C. Similar oscillations were observed in subcutaneous tissue without tumor. An average temperature increment of 0.5–1.0°C was observed when a tumor was transferred from the subcutaneous to the abdominal location. Gradients larger than 1°C were observed within the same tumor in locations only a few millimeters distance from each other. The nonuniformity in temperature within normothermic tumors was exaggerated during hyperthermia. No appreciable change in temperature gradients was seen within a normothermic tumor when tumor blood flow was doubled or reduced to one-third of the basal level. Hyperthermia increased both volume and temperature of tumor efferent blood. As expected, decrease or increase in blood flow during hyperthermia increased or decreased tumor temperature, respectively, but substantial temperature gradients up to 2°C still persisted within adjacent regions. The extent of temperature changes in the tumor could not be correlated with a known change in blood supply. A pulse of cold serum into the tumor afferent artery produced a substantial reduction of tumor blood flow, but only a small depression in tumor temperatures, and a very small change in tumor temperature gradients. No appreciable modification could be brought about in tumor temperature levels and temperature gradients within the tumor by pulses of cold serum in the afferent artery during hyperthermia. After external cooling of the tumor, the time necessary to compensate for temperature depression did not correlate with either the reduction of temperature or with the thickness of the tumor tissue separating the thermistor from the cold source. The results indicate extensive anisotropy of temperature and blood distribution within growing neoplastic tissue and suggest that heat transfer by convection within the tumor is much less effective than it is commonly assumed.—JNCI 1982; 68:519–533.

In human and rodent tumors survival of cancer cells is sharply reduced at 42°C while normal tissues do not suffer irreparable damage. At temperature above 42°C, although neoplastic cells are more rapidly damaged, normal tissues are also severely affected. Temperatures below 42°C but above physiologic levels may accelerate growth and dissemination of neoplastic cells (*1–5*). These observations indicate the need for accurate knowledge of temperature distribution within tumors in view of the importance that thermography and hyperthermia have acquired in cancer detection and treatment.

In the experiments reported here, we evaluated the temperature gradients of the virgin mammary gland and of mammary tumors under normothermia, hypothermia, and hyperthermia in rats. We also evaluated the effects of changes in local blood perfusion rates on temperature gradients within the tumor and assessed the implications of the results on thermography and hyperthermia.

MATERIALS AND METHODS

Experimental approach.—The temperature gradients within normothermic tumors were measured continuously by three thermistors from the 1st day of tumor transplantation until the host died 15–18 days later. The thermistors were incorporated by the growing tumor tissue; therefore, damages due to the insertion of measuring probes were avoided. The animal was kept in an appropriate cage and was free to move during the experimental period (*6*).

Temperature gradients during hyperthermia were measured in anesthetized rats. Heat was produced by an electric bulb with appropriate shielding and controlled energy input. The distance between heat source and skin was 20 cm. The animal was shielded by styrofoam, and only the skin covering the tumors was directly exposed to heat. Tumors grown at the extremity of a vascular pedicle (*7*) were utilized to measure volume and temperature of blood leaving the tumor. Changes in temperature gradients within tumors were obtained by rapid cooling of the tumor. In the first approach, a pulse of cold serum was injected in the artery feeding the tumor. In the second approach, 300 μl ethanol was applied to the skin covering the tumor and was then rapidly evaporated during 2 minutes by a stream of air.

Animals and tumors.—Randombred Sprague-Dawley female rats 3–4 months old, 200–250 g body weight were utilized (Small Animal Section, Veterinary Resources Branch, Division of Research Services, NIH, Bethesda, Md.). W256 was used as a model in all experiments. The tumor was transplanted from the NIH line, carried in Sprague-Dawley females for almost 5 decades (*8*) in subcutaneous implants alternated with intraperitoneal passages at a ratio of 5:1. The rats were anesthetized with ether for

minor surgery, such as preparation of the subcutaneous pouch or positioning of thermistors; otherwise, 50 mg pentobarbital/kg body weight, or 1 mg urethan/kg body weight was used for anesthesia. The animals were kept in a room with a 12-hour light cycle, from 6 a.m. to 6 p.m. light and from 6 p.m. to 6 a.m. dark. Room temperature was controlled at 24±1°C. The temperature of the operating table was 30±1°C. No precaution was taken to prevent heat loss from anesthetized animals. In long-term experiments tumor temperature was recorded every 30 minutes; in short-term experiments, every 10–30 seconds.

Tumor preparations.—Measurements of temperature gradients were conducted on subcutaneous transplants during the life-span of the tumor. A pouch was prepared in the subcutaneous tissue of the lumbar region, and three thermistors bound together at a distance of approximately 0.5 cm from each other were placed in it with a few fragments of W256. The wires of the thermistors were driven through a subcutaneous tunnel to the nuchal region and then out of the animal into a stainless steel spring for protection. One end of the spring was fixed to the skin of the nuchal region, and the opposite end was attached to the top of the cage that rested on a 30×30-cm plastic base. The length of the spring was adjusted to permit the animal to move at will around the cage. An appropriate device previously described (*6*) compensated for the torsion produced by the movements.

The temperature of the host was also continuously monitored by a thermistor placed in the abdominal cavity. The wire of this thermistor exited from the lumbar region opposite to the tumor implant and joined the wires of the tumor thermistors in the subcutaneous tunnel and the protective stainless spring. This preparation permitted continuous temperature monitoring during the life-span of the tumor.

In experiments where measurements started only after the tumor had grown to incorporate the thermistors, the wires of the thermistors were kept in a pouch of the nuchal region until the time of measurement.

Experiments that involved a pulse of cold serum were performed on a tumor preparation where *a*) three thermistors were incorporated by the tumor, *b*) the tumor was connected to the host by one artery and one vein only so that all the blood flowing through the tumor could be collected when the vein was cannulated, *c*) the tumor was grown subcutaneously in a paraffin sack to prevent infiltration of the surrounding tissues so that the measured blood supply pertained exclusively to the tumor, and *d*) the experiment was performed in an anesthetized animal.

A preparation with these characteristics was in the past obtained by transplanting the tumor at the distal end of the ovarian pedicle (*7*). In the experiments with a pulse of cold serum, however, the rat ovarian artery was too small to accept any available catheter without being occluded. We therefore developed a second system that utilizes the artery and vein of the left inguinal mammary gland as blood supplier to the transplanted tumor.

As previously described (*9*), in this system an arterial and venous branch of the superficial epigastric vessels reach the second inguinal mammary gland as a pair of vessels that run isolated in the adipose tissue and penetrate the gland through a circumscribed area. As a first step, this vascular pedicle was isolated with a fragment of gland about 0.5 cm^3 at the distal extremity. Then about 0.1 ml of tumor slurry was injected into the isolated gland fragment, and three thermistors were anchored around it. The implant was then enveloped by a sheet of paraffin (American Can Company, Marathon Products, Neenah, Wisc.) and placed into a pouch of the subcutaneous tissue. The purpose of the paraffin envelope was to avoid invasion of and vascular input from the surrounding tissues.

After 4–5 days, the subcutaneous pouch was opened and the paraffin sack was discarded. At this time, the tumor appeared like a ball about 1 cm in diameter. Inspection permitted an assessment of its growth and allowed us to correct the thermistor's position when necessary. The preparation was again placed in a paraffin sack and returned to the subcutaneous pouch. During the following 4–5 days, the tumor volume doubled, the thermistors were completely incorporated by the growing tissue, and the preparation was ready for measurements.

The abdominal cavity of the anesthetized rat was opened and the iliac vessels exposed. The femoral artery and the collateral branches leaving the third distal of the left iliac artery were tied off, except for the superficial epigastric and rectal branches. The right iliac artery was then tied off at the caudal extremity. A catheter (PE10; Clay-Adams Inc., New York, N.Y.) was inserted and the tip positioned a few millimeters from the origin of the epigastric artery feeding the tumor. The catheter was heat pulled to reach an outside diameter about one-fifth of the original. This kind of catheter is sufficient to permit the injection of 2 ml serum within 2 minutes and does not obstruct the blood supply to the tumor, as proved by the unaltered volume of tumor efferent blood after catheter insertion.

Figure 1 summarizes the conditions necessary for the cold pulse experiment. In the preliminary experiments the catheter delivering the cold pulse was positioned into the iliac artery via the left external carotid and the aorta. This procedure was simpler and less traumatic than the modified procedure, but the results were unsatisfactory. Only minimal changes in temperature gradients were recorded within the tumor, presumably because the cold serum flowing through a thin catheter immersed in warm blood through several centimeters became too warm by the time it reached the tumor capillary system. With the modified procedure, however, a pulse of cold serum could be rapidly delivered to the vascular system of the tumor in a reliable and consistent way.

The reduction in tumor temperature by an external coolant was obtained with 300 μl of ethanol dispersed in 30 seconds over the skin overlaying the tumor and immediately evaporated by a constant stream of room air directed on the wet surface for 2 minutes. The procedure induced sharp temperature reduction in the tissues covered by the skin.

At the end of the experiment, we measured accurately with a caliper the thickness of the tumor tissue that separated each thermistor from the tumor surface facing the skin, or from the abdominal wall, or from each other (fig. 2).

Changes in tumor blood supply.—The vein draining the tumor grown at the extremity of a vascular pedicle was cannulated and the volume of efferent blood was measured continusouly throughout the experiment. Arterial pressure was kept constant by reintroducing blood via the external jugular vein in about the same amount as that lost by the tumor vein (fig. 1A). The blood temperature was stabilized at 35.5°C and was returned to the animal. When the volume of blood pumped into the jugular vein was reduced, hypovolemia occurred, the aortic pressure decreased, and the flow of tumor efferent blood diminished. When the aortic pressure was kept at 50 mm Hg, the efferent tumor blood was usually reduced to one half of the volume measured at the physiologic aortic pressure of about 100 mm Hg. When the volume of blood return to the jugular vein was increased, hypervolemia occurred and tumor efferent blood volume rose. An aortic pressure of 140 mm Hg usually doubled the outflow of tumor blood measured at physiologic pressure.

Measuring devices.—Tumor temperature was measured with epoxy-coated linear thermistors (#44201; Yellow Spring Instrument Co., Yellow Spring, Ohio). The response time of the thermistor is 1 second in unstirred oil and 10 seconds in still air. A bridge circuit containing the thermistor in one arm was built according to the suggestions of the manufacturers of the thermistor. The bridge circuit, balanced at a low reference temperature, gave an output proportional to the temperature change. When the bridge circuit was calibrated correctly, deviation from the true temperature was less than 0.1°C within the temperature ranges of the experiment. The unbalanced output of the circuit was connected to a recorder (Autodata Nine; Acurex, Mountain View, Calif.). A mercury-in-glass thermometer corrected by the Institute for Basic Standards (National Bureau of Standards, U.S. Department of Commerce, Washington, D.C.) was used to calibrate the thermistors. Temperature changes due to self-heating of the thermistors were negligible. The thermistors were calibrated in water before implantation and again at the end of each experiment.

The thermistor wires were carefully isolated and contained within a polyethylene catheter (PE10). The area of tissue in contact with the sensitive surface of the thermistor was estimated to be about 0.5 mm in diameter.

RESULTS

Temperature Gradients in the Virgin Mammary Gland

For the purpose of background information, the temperature of the rat's second inguinal mammary gland was measured with two thermistors—one located between the gland and the abdominal muscle and the other located between the gland and the skin. This was considered the most effective way of obtaining data with minimum damage to the gland that is spread out as a sheet in the subcutaneous tissue. Each experiment lasted for 5 days while the animals were free to move in an appropriate cage. Text-figure 1 shows 3 days of recording of one of four experiments.

A circadian rhythm was evident in all the mammary glands with the highest temperatures toward midnight and the lowest at noon. The skin side of the gland was consistently colder, as one would expect, but the differences between skin and abdominal sides did not follow any obvious pattern. The amplitude of these differences was largest in the experiment of text-figure 1, where differentials of 2°C were occasionally observed. In three other experiments, however, the largest differences remained within 0.7°C.

Comparisons between temperatures of the second inguinal and third thoracic glands were also made with two thermistors, both placed either on the skin side or on the abdominal side of the glands. In four out of six experiments, the temperature tracings overlapped or intersected each other indicating that the temperature gradients were not substantially different for the two glands. In one animal, the thoracic gland was consistently up to 1°C warmer than the inguinal gland over the 5-day measurement period, and in another animal the reverse condition was observed (data not shown).

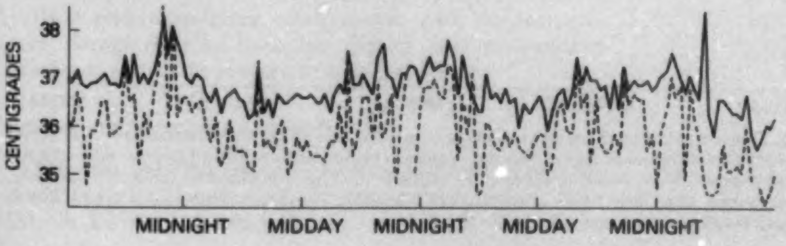
From the experiments aimed at assessing the temperature gradients of the normal mammary gland of rats kept at room temperature, we concluded that differences of about 0.7°C between the skin side and abdominal wall side of the gland were common and differences up to 2°C were possible.

Temperature Gradients Within Normothermic Tumors

Temperature Gradients at the Site of Tumor Implant

As a preliminary experiment, the temperature gradients of the subcutaneous tissue were recorded by three thermistors in the lumbar region where the tumors were transplanted. A fourth thermistor was placed in the abdominal cavity. In three separate experiments temperatures were recorded for 15 consecutive days, the time required by W256 to kill or make the animal moribund.

The circadian rhythm was not evident until 48 hours after the implant of the three thermistors. The abdomen was consistently warmer than the subcutaneous region, and the largest difference observed in the three experiments was 2.2°C. The tracings of the the three subcutaneous thermistors were often overlapping or intersecting each other. Oc-



TEXT-FIGURE 1.—Temperature gradients in the left second inguinal mammary gland of a virgin, female 170-g rat. Measurements started 2 days after thermistors were implanted. ----=temperature recording between the skin and the gland. ——=temperatures between abdominal wall and gland surface. *Note* the circadian rhythm of temperature changes with zenith at midnight and nadir at midday. Room temperatures varied between 25.5 and 27.5°C with the coldest peaks at midnight.

casionally, there were differences up to 2.0°C persisting for two to three recordings at 30-minute intervals, suggesting that these gradients were indeed real and possibly of physiologic significance.

Temperature Gradients Within the Tumor

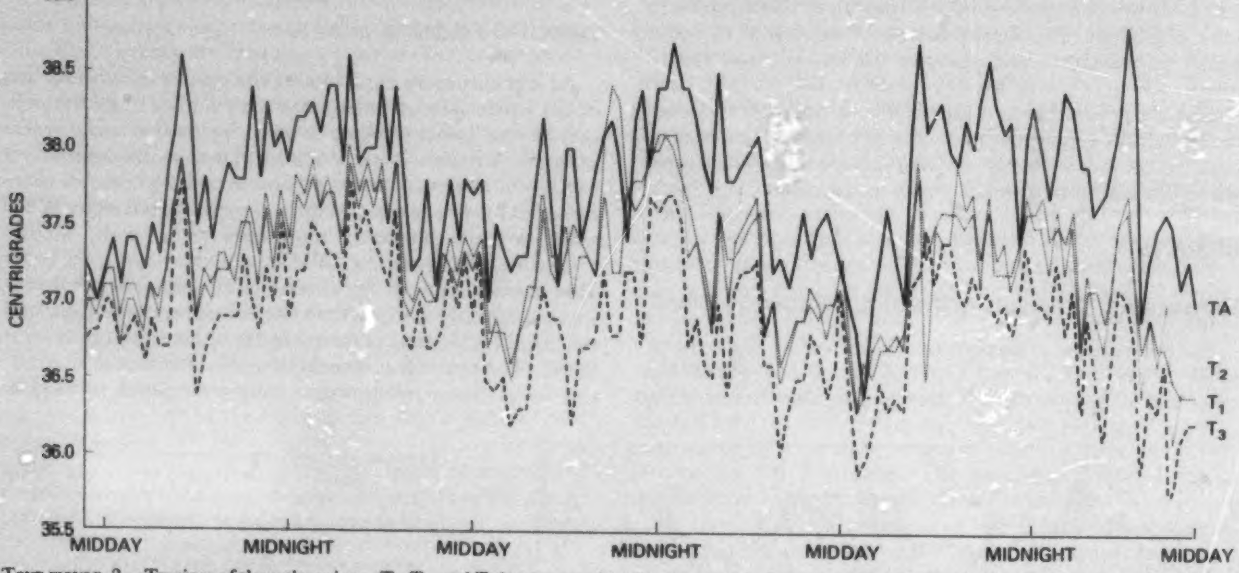
The W256 was implanted in the lumbar region, and as it grew it incorporated the three thermistors. The temperature was recorded from the day of the implant until the tumor killed the animal. At the time of tumor implant, a thermistor was also placed in the abdominal cavity to monitor host temperature. The objective was to measure the range of temperature changes during tumor growth and to assess the possible influence of necrosis on these changes. Indeed, as the tumors grew, areas of necrotic tissue around the thermistor were increasing in number to the point where the thermistors were embedded almost completely in necrotic material during the last days of the host's life.

Text-figure 2 shows a recording, from day 6 to day 9 after transplantation, obtained in one of four experiments. All tumors consistently showed circadian rhythm in synchrony with that of the host, i.e., the highest temperatures occurred at midnight and the lowest temperatures occurred at midday. Differences between the highest and lowest temperatures recorded during the circadian changes are reported (table 1) from the time of tumor implant until the death of the animal. They are comparable with the changes observed in the subcutaneous tissue of the lumbar region where the tumor was transplanted. Surprisingly, no substantial modification of these gradients was apparent during the increase in tumor size with prevalence of necrosis around the thermistors. As the host became moribund, the absolute value of body temperature decreased. However, substantial temperature gradients within the tumor persisted until the last day of host survival (table 1).

At any given time, temperature gradients were also consistently present among different areas of the same tumor (text-figure 2), with ranges comparable to those observed in the subcutaneous tissue. As expected, thermistors closer to the skin surface of the tumor usually measured the lowest temperatures. Only exceptionally, and for a brief period of time, was the temperature of the subcutaneous tumor equal to or higher than that of the abdomen. When the animal became moribund, the amplitude of temperature changes was reduced both during the circadian rhythm and within the tumor at any given time. Occasionally, the tumor was warmer than the abdomen during the last 48–72 hours of host survival.

Temperature Gradients in the Same Tumor Grown Consecutively in Two Locations

Each tumor was grown at the extremity of a vascular pedicle and incorporated three thermistors. Initially, the tumor was located in a pouch of the subcutaneous tissue and was enveloped in a paraffin bag. When the tumor size was sufficiently large to ensure incorporation of the three thermistors, the temperature gradients were recorded for 2 days. Then the tumor was transferred from the subcutaneous pouch into the abdominal cavity and the temperature gradients were recorded for 2 additional days. The transfer of the tumor from the subcutaneous to the abdominal location was possible because the paraffin bag, in which the tumor grew, kept it isolated from the surrounding tissues. Moreover, the location of the tumor at the extremity of the long



TEXT-FIGURE 2.—Tracings of three thermistors T_1, T_2, and T_3 incorporated by the tumor and of one thermistor located in the abdominal cavity (TA) from day 6 to day 9 for a subcutaneous W256 growing in the left lumbar region of the rat. *Note* the circadian rhythm, with zenith and nadir at midnight and midday, respectively, synchronous with that of the abdominal cavity which is consistently warmer than the subcutaneous tumor. Occasionally, temperature differences among the three tumor thermistors were rather large (table 1). Distances of thermistors from tumor surface: T_1=20 mm, T_2= 10 mm, T_3=3 mm. Thickness of skin covering tumor=1 mm. Tumor weight at animal's death=38.3 g.

[c] Three thermistors were placed in the subcutaneous tissue of the lumbar region, no tumor.

vascular pedicle allowed mobilization without impairment of blood supply. During the determinations the animal was kept in the same cage and was free to move. The tumor temperature was recorded every 30 minutes.

The results of the three experiments show that in the abdominal location the average tumor temperature was 0.5–1.0°C higher than in the subcutaneous area, but temperature changes due to circadian rhythm and temperature gradients within the tumor remained unchanged.

Temperature Gradients Around Tumors

Temperature differences between the skin surface and the abdominal wall surface of the tumor were recorded in tumors grown at the end of vascular pedicles. Since these tumors were grown in a pouch of the subcutaneous tissue enveloped by a paraffin sack, the thermistors were placed between the paraffin and the skin or the paraffin and the abdominal wall. The tumor surface was therefore separated from the thermistor by a sheet of paraffin about 100 μm thick. Temperature was recorded in the anesthetized animals for periods of 20–40 minutes. The gradients observed in six experiments varied from 0.4 to 2.1°C (table 2), and as expected the colder temperatures were consistently registered by the skin-side thermistor. The temperature gradients around the tumor did not show any substantial difference from the gradients observed in the normal subcutaneous tissue or within the tumor.

Temperature Gradients Within Hyperthermic Tumors

The objective of these experiments was to assess the effect of hyperthermia on the existence and magnitude of temperature gradients within tumors.

Heat was applied to the skin overlaying the tumor until the temperature recorded by one of the thermistors reached the desired level. The energy input to the lamp was then regulated to maintain this level constantly for 30–60 minutes. The temperatures measured by the three thermistors embedded within the tumor were recorded before, during, and after the heat application until the tumor temperature had returned to basal levels.

The curves obtained in one experiment are shown in text-figure 3. Table 3 presents the summary of 10 experiments, where the highest gradients recorded before, during, and after heat application are presented. These gradients are compared with the thickness of the neoplastic tissue separating each thermistor from the skin surface of the tumor, closest to the heat source, from the abdominal wall surface, farthest from the heat source, and the thickness of the neoplastic tissue separating the thermistors from each other.

The nonuniformity of temperature that existed in normothermic tumors was exaggerated during hyperthermia. In 8 of 10 experiments, temperature gradients larger than 1°C were observed within tumors at locations only a few millimeters distant from each other. The time needed to reach the highest temperature also varied among the three thermistors within the same tumor. However, any change in the heat input occurring during hyperthermia was promptly reflected in the temperature recorded by each thermistor (text-fig. 3). Once the temperature gradients were stabilized,

TABLE 2.—*Maximal temperature gradients around a W256 during normothermia*

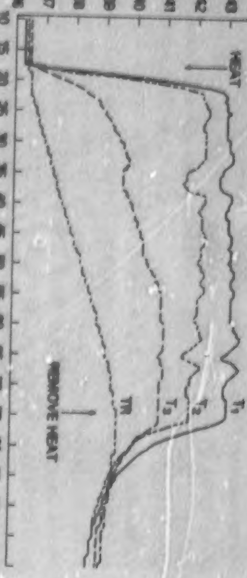
1/3.4	20	0.7
2/2.3	20	0.6
3/2.4	20	0.4
4/5.1	35	1.0
5/2.3	25	1.8
6/3.5	40	2.1

[a] T_{AB}=temperature recorded by a thermistor placed between the tumor and the abdominal wall. T_{SK}=temperature recorded by a thermistor placed between the tumor and the rat's skin.



TEXT-FIGURE 3.—Temperature gradients of a 3.7-g W256 were measured first under physiologic conditions, then heat was applied to bring up and maintain the temperature of one thermistor at ≈43°C. During hyperthermia the temperature differences among the three thermistors became more accentuated. When heat was removed the gradients returned roughly to the starting levels within ≈1 hr. The times required to reach maximum temperatures were quite different among the three thermistors. *Note*, however, the prompt and simultaneous response of all three thermistors at changes of heat input. Distance of thermistors from skin surface of tumor: T_1=7 mm, T_2=3 mm, T_3=2 mm. T_R=rectal temperature.

they did not change appreciably whether the hyperthermia lasted 1 or 3 hours. Moreover, the correlation coefficients, calculated to assess the relationship between temperature changes and thickness of neoplastic tissue separating the thermistors from each other, or from the tumor surfaces, failed to show a consistent trend (table 3).

Text-figure 4 shows the curves obtained in one experiment when the tumor was in the abdominal cavity and heat was applied by a lamp placed 20 cm from the abdominal wall. Note that about a 4.5°C difference was observed between the recordings of two thermistors placed 1.3 cm apart in the 12.5-g tumor about 20 minutes after heating. When the heat was removed, the temperature gradients returned to about the levels prior to heating. This behavior was observed in three separate experiments, although the extent of temperature difference varied.

Influence of Blood Flow on Temperature Gradients of Normothermic and Hyperthermic Tumors

To evaluate changes in the temperature gradients produced by an increase or decrease of blood supply, we used in the first group of experiments normothermic tumors grown at the extremity of a vascular pedicle. The blood supply was measured as the volume of blood collected from the efferent tumor vein. Increase or decrease of blood supply was obtained by hypervolemia or hypovolemia induction in the host, respectively. The results of one of three experiments are shown in text-figure 5, where substantial changes in blood flow were followed by minimal changes in the temperature gradients within the tumor.

In the second group of experiments we used hyperthermic tumors. The energy input of the heat lamp was adjusted to bring the tumor temperature to 39–40°C as recorded by one thermistor; then the blood supply to the tumor was altered while the heat supply was kept constant. Text-figure 6 shows the results of one experiment where the application of heat produced increases of both volume and temperature of the tumor efferent blood. As the blood flow was stabilized at

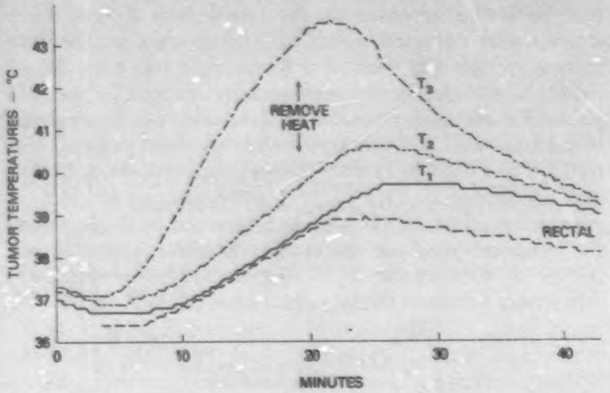
[a] Experiments 1–7: tumors grown at the extremity of a vascular pedicle; experiments 8–10: subcutaneously transplanted tumors.

[b] Base-line temperature was recorded by thermistors T_1, T_2, and T_3 for 30 min. Heat was applied until T_1 reached the highest temperature selected for the experiment (*see* column Heat output of the lamp was regulated to keep T_1 at constant temperature. Heat was removed after steady state prevailed for about 15 min; then the tumor temperature was allowed stabilize and gradients were measured.

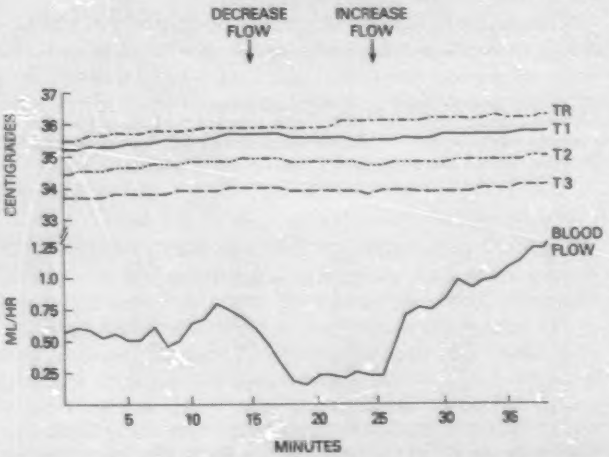
[c] At the end of the experiment the tumor was cut to expose position of thermistors. Distance of thermistor tip from the tumor surface in contact with skin (DS) or abdominal wall (D was measured by caliper (*see* fig. 2).

[d] ND=not determined.

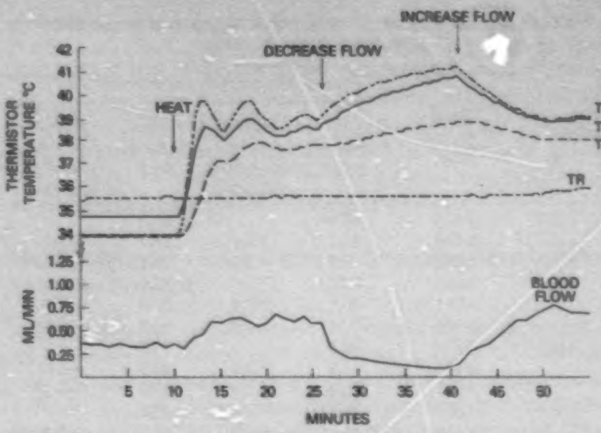
the new level, hypovolemia was induced and a reduction of blood flow was obtained. Promptly, an increment of tumor temperature followed. When stabilization of this new condition was obtained, hypervolemia was induced and the tumor temperature subsequently decreased. During the modification of blood supply, the temperature gradients within the tumor persisted. The observations reported in text-figure 6 were consistently reproduced in six separate experiments performed under identical conditions.



TEXT-FIGURE 4.—Temperature gradients of a 12.5-g W256 grown at the extremity of the ovarian pedicle of the rat and kept in the abdominal cavity. Heat was applied by a lamp located 20 cm away from the abdominal wall. *Note* that during hyperthermia the temperature differences among tumor thermistors became more accentuated. When heat was removed the gradients returned to about the initial levels. Distances of thermistors from the tumor surface: T_1=9 mm, T_2=9 mm, T_3=8 mm. Tumor size=2.5×3.0×1.8 cm.



TEXT-FIGURE 5.—Relationship between changes in blood flow and temperature gradients within a 2.4-g normothermic tumor. The gradients showed minimal changes despite a doubling or a reduction to one-third of the basal tumor blood flow. T_1, T_2, and T_3 correspond to thermistors 1, 2, and 3.



TEXT-FIGURE 6.—Relationship between blood flow changes and temperature gradients within hyperthermic tumors. Tumor temperature was increased to the desired level, then the power input to the lamp was kept constant, and changes in blood flow by hypovolemia or hypervolemia were produced. *Note* that application of heat sufficient to elevate tumor temperature to ≈39°C resulted in the increase of tumor blood supply. When a depression of blood supply was induced, the temperature of the tumor increased and the reverse was observed when the blood supply was enhanced. The temperature gradients, however, persisted throughout. T_1, T_2, and T_3 designate tumor thermistors. T_R = rectal temperature.

The data obtained in the hyperthermic tumor experiments are reported in table 4. In the blood flow column three values are given for each experiment. The first one indicates the blood flow stabilized after the tumor temperature was brought to 39–40°C, the second value indicates reduction in the blood flow during hypovolemia, and the third value is the blood flow increment after hypervolemia. For each blood flow value the highest and lowest temperatures recorded by the thermistors embedded in the tumor are indicated in the adjacent columns. A change in blood flow produced a prompt change consistently in the local temperature of the tumor subjected to a constant heat input. The range of this change varied among tumors and also substantially varied within the same tumor. For instance, in the first experiment (table 4) a blood flow reduction of about 80% produced in the warnest area an increment of tumor temperature of 2.1°C, which was abolished by the subsequent increase in flood flow. In the coldest area of the tumor, however, the decreased blood flow produced a temperature increase of only 0.2°C, overcompensated for by the subsequent increase of blood flow that resulted in a 0.6°C drop in temperature.

There was no reproducible pattern among several tumors in the modification of temperature gradients following blood supply changes. Despite the prompt temperature response to any modification in blood flow, very large blood flow changes were necessary to produce relatively modest temperature changes. This phenomenon indicates that conductive heat transfer in the tumor prevails over convective heat transfer. However, we could not establish an exact relationship between the extent of temperature changes in a tumor and a known change in blood supply.

Modification of Tumor Temperature Gradients by an Intra-arterial Pulse of Cold Serum

With these experiments we attempted to assess the effect on tumor temperature gradients of an abrupt modification in the temperature of the blood entering the tumor. The final objective was an evaluation of local tissue perfusion derived from the observed changes.

TABLE 4.—*Relationship between blood supply and temperature gradients within a tumor*

[a] For each experiment three blood flow values are reported: when heat was applied to the tumor, when reduction in blood flow was induced, and when blood flow was returned to initial or higher levels.

[b] Temperatures measured when three different levels of blood supply to the tumor were kept constant for at least 15 min.

[c] Maximal temperature differences induced in tumors by variations in blood supply.

Normothermic Tumors

We used the preparation with a tumor growing at the extremity of the vascular pedicle and incorporating three thermistors. The rat was anesthetized, the abdominal cavity opened, and a catheter positioned in the left iliac artery and readied for the rapid injection of cold serum into the tumor afferent artery as described in "Materials and Methods" (fig. 1). Finally, the efferent vein of the tumor was cannulated, and the determination of blood flow was started.

After base-line values for tumor and host temperatures as well as for blood flow were established for 20–40 minutes, a pulse of cold serum was given and the temperature changes in the tumor and rectum were recorded every 30 seconds until approximate base-line values returned. Preliminary tests for duration, volume, and temperature of serum pulse showed that the best responses were obtained when volume was kept constant at 2 ml, the pulsed serum had the temperature of melting ice and duration was 0.5–2 minutes.

Text-figure 7 shows the temperature gradients obtained from one experiment. The results of eight more experiments summarized in table 5 give the maximal temperature depressions produced by the cold pulse in three regions of the tumor containing the three thermistors as compared to the gradients measured in the rectum and in the tumor efferent blood of the same animal. Regardless of the temperature of the pulsed serum or the duration of the pulse, the temperature reduction recorded in the tumor was always much smaller and occurred much later than that in the host rectum, which was used as a physiologic reference. Blood supply to the tumors was substantially reduced by the cold pulse. For instance, in the case shown in text-figure 7 the blood flow was 21.7 ml/hr/g before the cold pulse, it was reduced to 1.6 ml/hr/g when blood temperature was lowest, and it returned to 23.2 ml/hr/g when efferent blood temperature reached 36°C. Although the cold pulse decreased the temperature of the tumor efferent blood by 2.3°C and the rectal temperature by 8.5°C, the largest temperature differences recorded in the tumor were 0.7, 0.7, and 0.4°C, respectively. Similar behavior is reported in table 5 for the other experiments. All tumors were relatively small and without evidence of necrosis around the thermistors as observed macroscopically at the end of each determination.

In three of the experiments a second pulse of cold plasma was injected about 10 minutes after the temperature depression of the first pulse was compensated. The range of temperature depression due to a second pulse was different from that obtained with the first stimulation, although the time required to reach the maximal temperature change was similar in most instances (table 6).

A major limitation in all these experiments was the inability to produce large temperature gradients in tumors,

TABLE 5.—*Temperature gradients in tumors receiving a pulse of cold serum in the afferent artery*

[a] Differences between tumor temperatures were measured by thermistors T_1, T_2, T_3, and T_R during the last 5 min before pulse and the lowest temperature measured after pulse. T_R: thermistor measured rectal temperature for physiologic reference.

[b] Times elapsed between the end of cold pulse and lowest temperature recording.

comparable to those observed, for instance, in the rectum. Differences of fractions of a centrigrade are less convincing and more prone to errors than larger gradients. Notwithstanding this limitation, it is clear that a substantial reduction of blood temperature produced relatively small temperature depression and gradients in the tumor, as opposed to a substantial reduction in a normal organ like the rectum. In contrast, however, the tumor temperature gradients last longer.

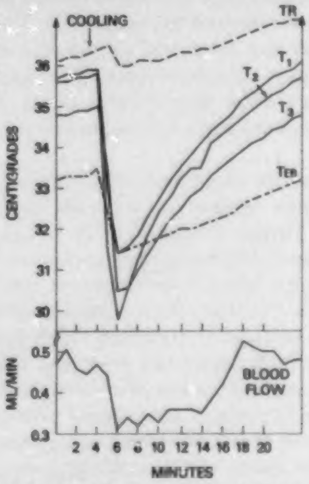
Hyperthermic Tumors

In four additional experiments a pulse of cold serum was given to tumors kept at a temperature of 41-42°C. Hyperthermia was induced 10-15 minutes prior to the pulse and maintained until the end of the determination. A pulse of cold serum in the tumor artery, however, did not produce any appreciable change in the temperature levels and gradients within hyperthermic tumors. Again, the poor blood supply may be responsible for the limited importance of heat convection on tumor temperature.

Modification of Tumor Temperature Gradients by an External Coolant

To overcome the difficulty of obtaining a substantial temperature depression with an arterial pulse of cold serum, we used an external coolant in the following experiments. Tumors incorporating three thermistors and grown at the distal extremity of the vascular pedicle were utilized. The efferent tumor vein was cannulated for continuous measurement of blood flow, then the tumor was rapidly cooled with the ethanol procedure (*see* "Materials and Methods"). A thermistor in the rectal cavity registered the host temperature during the entire experiment. Text-figure 8 reports the data collected in one of five experiments, and table 7 summarizes the maximal temperature depression produced by the cold stimulus and the time required for the temperature to return to steady-state level.

The temperature gradients obtained with this procedure were larger than those obtained with the intra-arterial pulse of cold serum. Maximal depression of tumor temperature



TEXT-FIGURE 8.—T_1, T_2, and T_3 are thermistors within the tumor, T_R in the rectum, and T_{EB} is the temperature of the tumor efferent blood. Temperature gradients within a 6.8-g W256 were obtained by ethanol cooling of the overlaying skin (*see* "Materials and Methods"). *Note* the rapid and extensive reduction of tumor temperature obtained with this procedure as compared with that obtained by the ia serum pulse (text-fig. 7). In this particular tumor the distances from the skin surface were T_1=3 mm, T_2=5 mm, and T_3=4 mm. In this tumor, as in others (table 7), there was no relationship between maximal temperature depression and the thickness of neoplastic tissue between the surface of the tumor facing the cooled skin and the thermistors. The shape of the curve representing the return of tissue temperature to original values was different for each thermistor. *Note* the substantial reduction of blood flow in the cooled tumor.

TABLE 7.—*Modification of tumor temperature by rapid cooling of the skin over the tumor*

[a] Differences between temperatures registered by thermistors T_1, T_2, T_3, and T_{EB} 5 min before cooling and the lowest temperature measurement after cooling. T_{EB}=thermistor in the tumor efferent blood.

[b] ND=not determined.

[c] Times elapsed between lowest temperature measurements and return to basal temperatures after ethanol cooling; t_1, t_2, t_3, and t_{EB} are time differences measured in tumors and in tumor efferent blood, respectively.

[d] Skin thickness was ≈1.0 mm in all cases.

[e] In these cases the temperature did not return to basal levels but stabilized at slightly lower levels.

from the ethanol applications on the skin was obtained within 3.5 minutes on the average. This parameter was obviously influenced by the distance of the tumor thermistors from the skin surface where the cooling process was applied. However, since the coolant was evaporated in 2 minutes the rate of temperature return to the original levels was most probably related to the blood flow around the thermistors and was relatively independent from the thermistor–skin surface distance. The temperature reequilibration time, therefore, gives an indication of the local efficacy of the blood supply.

As expected, the curves representing the temperature reequilibration varied from one thermistor to another (text-fig. 8). The time required to compensate for each gradient within a tumor also presented substantial differences. For instance, in tumor 1 (table 7) it took 12 minutes to compensate a 6.4°C gradient as contrasted to a 4.0°C gradient measured in two separate regions by thermistors 1 and 2, respectively.

The temperature depression could not be related to the amount of tissue separating the cold source from each thermistor. In tumor 4 (table 7), for instance, almost the same temperature depression was measured by thermistors 1 and 2, although about twice as much tumor tissue separated thermistor 2 as that which separated thermistor 1 from the cooled skin surface. Alternatively, in tumor 2 thermistors 2 and 3 were both separated from the skin by a 8-mm thickness of tissue, and the temperature depression registered by thermistor 3 was about twice that of thermistor 2. In all cases, a reduction of efferent blood was produced by cooling the tumor. The range of this reduction varied from 25 to 40% of the precooling level.

Because the temperature depression was obtained in a few minutes and occurred simultaneously with a substantial reduction in blood flow, we concluded that differences in resumption of local perfusion were instrumental in determining the size of the temperature gradients observed among different areas of the same tumor. On the basis of this assumption, an estimate of local perfusion was obtained.

Estimation of Flow Distribution Within Tumors

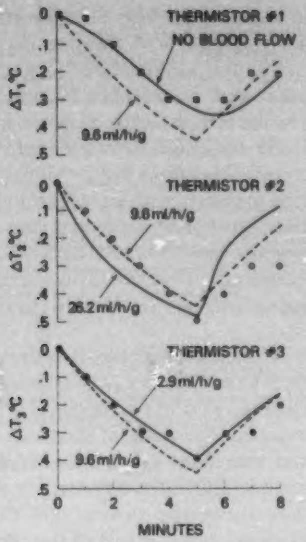
The partition of blood supply within a tumor was estimated with the use of a mathematical model (*10*) that considers the rat as a system comprised of a tumor and normal tissues, represented by anatomically interconnected compartments. (For details, *see* "Appendix.") The tumor is divided into three compartments related to the three thermistors, and the temperature in each compartment is predicted as a function of time after a cold pulse of serum into the tumor artery or after the skin cooling by alcohol. The blood flow distribution into these three tissue compartments is estimated by fitting the model predictions with our data.

From the temperature drop values (table 5) after a pulse of cold serum, the flow distributions shown in table 8 were obtained. Text-figure 9 shows the comparison between the data for a 2.3-g tumor (tumor 8 in table 8) and the predictions of our model. The solid lines were obtained by assuming that 0, 90, and 10% of the afferent blood was flowing into each of the three compartments, respectively, and the dotted lines were obtained by assuming that the blood flow was uniform throughout the tumor. Visual comparison between temperature decrease and blood flow curves emphasize the nonuniform blood distribution for tumor 8 (text-fig. 9). Similar charts (not presented) were obtained for each of tumors 1–8 (table 8).

We calculated the blood flow distribution for tumors 8–10 (table 8) from the data on temperature drop subsequent to skin cooling (table 7). For example, for a 6.8-g tumor (tumor 10, table 8 and text-figure 10), the solid lines were calculated by assuming that the blood flow was distributed in the areas around the three thermistors as 50, 0, and 50% of the efferent tumor blood, respectively, whereas the dotted line was drawn by assuming uniform flow throughout the tumor. Again, the anisotropy of blood distribution around the thermistors is evident. The small differences in temperature prediction shown in text-figures 9 and 10 also emphasize that thermal diffusion and not convection is the major event in heat transfer within tumors.

DISCUSSION

The temperature gradients in the normal mammary gland of the virgin rat were comparable to those observed by Møller and Bojsen (*11*). The temperature difference within the gland was usually less than 1°C, without consist-



TEXT-FIGURE 9.—Comparison of mathematical model predictions with the experimental data (tumor 8, table 8). The points (□, ○, ●) on each of the three graphs refer to the tumor temperature decrease measured by thermistors 1, 2, and 3, respectively, following the injection of cold serum. -----, obtained by assuming uniform blood flow throughout the tumor, in this case 9.6 ml/hr/g. ——, obtained by assuming 0, 90% (26.2 ml/hr/g), and 10% (2.9 ml/hr/g) blood supply around thermistors 1, 2, and 3, resp. Similar curves were obtained for each tumor in table 8. Difference between experimental data and model predictions, with the assumption of uniform flow, was 0.023°C. Difference between experimental data and model predictions, with the assumption of nonuniform flow, was 0.020°C.

ent differences among glands. Temperature gradients within tumors were roughly similar to the gradients of the subcutaneous space where the tumors were transplanted. Both normal and neoplastic mammary tissues exhibited a clear circadian rhythm with the zenith at about midnight and nadir at about midday; the difference between the two could reach 3°C. It was surprising that both circadian rhythm and temperature gradients persisted in large tumors where thermistors were embedded in necrotic material. We have no explanation for this unexpected finding that was consistent in four separate experiments (table 1) and contrasted with previous observations (*11*).

Temperature gradients within the tumor increased under hyperthermic conditions. Since convective heat dissipation in the body is dependent on blood flow, and conductive heat transfer is determined by thermal conductivity of tissues, the increment of the measured temperature gradients suggests that convective heat transfer in tumors is inefficient.

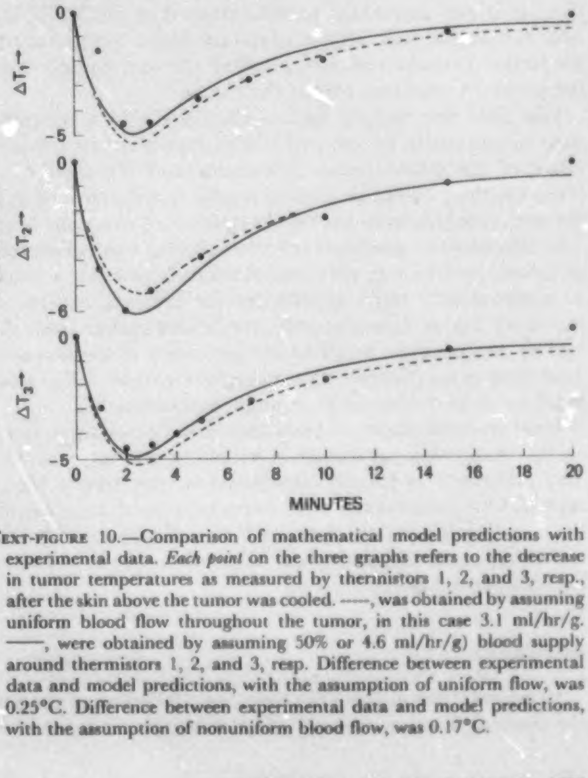
In hyperthermic tumors an increase in blood flow cooled the tumor as expected. From the data of table 4 one can calculate that on the average an increase of 1 ml blood per gram of tissue per hour in the flow rate will cool the tumor by 0.16°C in the highest temperature regions. In the majority of tumors studied, the blood flow, measured by collecting the efferent blood from the tumor vein of tissue-isolated preparations, varied between 10 and 15 ml/hr/g. These volumes are three- to fivefold lower than the supply to a parenchymatous organ such as the liver (*12*). A doubling of tumor blood supply was the largest increment we could experimentally obtain by resorting to a hypervolemia level in the host that was outside physiologic limits and increased the arterial blood pressure by about 50 mm Hg. If a doubling of the blood flow to the tumor is the maximum possible

TABLE 8.—*Blood flow distribution within a tumor estimated from the temperature gradients induced by an intra-arterial cold serum pulse (tumors 1-8) or skin cooling by ethanol (tumors 9-12)*

Tumor No./ wt, g	Blood supply, ml/hr[a]	Blood flow, % of total supply estimated for each tumor area surrounding a thermistor[b]		
		T_1	T_2	T_3
1/2.3	11.0	90	0	10
2/2.2	14.3	33	33	33
3/2.1	17.6	10	0	90
4/4.2	44.5	90	0	10
5/1.5	41.2	90	0	10
6/2.4	18.5	90	0	10
7/2.4	29.5	70	30	0
8/2.3	22.1	0	90	10
9/2.3	34.5	0	90	10
10/6.8	48.9	50	0	50
11/7.6	50.9	20	30	50
12/1.6	30.5	50	0	50

[a] Measured by cannulation of the tumor efferent vein for tumors 1–8 (tissue-isolated preparations) and calculated for tumors 9–12 (sc implants). From previous determinations (7), the relationship between blood flow and tumor weight in W256 is: log(flow/weight) = 1.419–0.678 log weight.

[b] A mathematical model previously developed (*10*) was utilized to evaluate the distribution of blood in the areas around thermistors T_1, T_2, and T_3 incorporated by each tumor (*see* tables 5, 7).



TEXT-FIGURE 10.—Comparison of mathematical model predictions with experimental data. *Each point* on the three graphs refers to the decrease in tumor temperatures as measured by thermistors 1, 2, and 3, resp., after the skin above the tumor was cooled. -----, was obtained by assuming uniform blood flow throughout the tumor, in this case 3.1 ml/hr/g. ——, were obtained by assuming 50% or 4.6 ml/hr/g) blood supply around thermistors 1, 2, and 3, resp. Difference between experimental data and model predictions, with the assumption of uniform flow, was 0.25°C. Difference between experimental data and model predictions, with the assumption of nonuniform blood flow, was 0.17°C.

increment that may be expected to occur in vivo, the efficiency of the tumor blood flow, both as a cooling or heat-carrying system, is rather low (*13, 14*).

Although the pulse of cold plasma substantially reduced the tumor blood flow and significantly decreased the temperature of tumor efferent blood, the reduction in tissue temperature was only a few tenths of a degree and with substantial anisotropy. The observation suggests that extensive arterial-venous shunts must exist which are able to exclude large sections of tumor tissue from efficient blood supply. Moreover, responses to subsequent pulses (table 6) indicate that the shunting varies with time and emphasize the importance of anisotropy in local blood distribution within tumors (*15, 16*).

The thermodilution experiments indicate that blood flow can be nearly zero in some region of a tumor and as much as threefold the average perfusion rate in other regions (table 8). Although the average perfusion rate decreases with the increase in tumor size, anisotropy of temperature distribution was quite evident in tumors of any size. Table 8 and text-figures 9 and 10 also indicate that a model utilizing homogeneous versus heterogeneous perfusion does not predict substantially different numerical values. This suggests that heat transfer in the tumor is dominated by conduction and not by convection. In a recent paper, Gibbs et al. (*17*) who explored temperature gradients within a tumor with a different method, reached a similar conclusion.

The size of temperature gradients observed in these experiments caution against the assumption that rapid and efficient heat distribution within the tumor can be achieved via the blood supply. Consequently, while it is more efficient to transfer heat to the tumor without relying solely on blood flow, it is also important to remember that the inefficient heat convection will help to maintain higher temperatures for longer periods, and will preserve the surprisingly high temperature gradients within the tumor.

Our data also caution against the belief that a temperature measurement in one region may represent the temperature of the whole tumor. Okamura and Reinhold (*18*) observed that for rat skin there is only a difference of 2°C between complete tolerance and maximum damage by heat. The temperature gradients observed during heat treatment of tumors in vivo may very well determine whether a lethal or a stimulatory effect is obtained for different regions of the same tumor. Consequently, the lowest rather than the highest temperature attained by the tumor is the determinant dose of an effective hyperthermic treatment; this dose hardly can be evaluated by a single measurement.

Heat-responsiveness of neoplastic cell populations is an easily predictable parameter in vitro but not in vivo (*19*). The difference is usually attributed to the tumor blood supply. Our data suggest that circumstances that influence heat conduction within the tumor or metabolism (*20*) control in vivo heat-responsiveness more effectively than events that influence heat convection.

APPENDIX

In general, two approaches have been followed to analyze the thermal dilution data (*21*). In the first one, it is assumed that after a cold serum pulse into a tumor, blood flow alone is responsible for the return to thermal equilibrium. This assumption is valid for well-perfused organs but fails for tumors with poor and anisotropic blood supply. In the second approach, the temperature changes are predicted by the bioheat transfer equation. Leaving aside the limitations of the bioheat transfer equation itself, this approach is useful only when applied to tissues with simple geometry. However, most tumors have complex geometry, are situated in a thermally asymmetric environment, and interact thermally with their surroundings. This condition is mathematically intractable; consequently, we resorted to the compartmental model.

The model was initially developed (*10*) to predict temperature distribution in tumors and normal tissue of rats during normothermia and hyperthermia. The model consists of nine compartments: three of them are constituted by the tissue around the three thermistors embedded in the tumor, one is the normal tissue adjacent to the tumor, one is the cooled skin above the tumor, one the skin on the adjacent normal tissue, one the rest of the skin, one the rest of the organism, and one is the blood pool. The temperature profile of each compartment is represented by a first-order ordinary differential equation, obtained by applying the general unsteady-state heat-balance equation: Net accumulation of thermal energy in each compartment=metabolic heat production+heat gained by conduction from interacting compartment(s)−heat lost to the perfusing blood−heat lost to the environment.

The detailed expression for each of the above heat-exchange terms and the values of the parameters incorporated into these terms for a tumor-bearing rat are given elsewhere (*22, 23*). During cooling by a cold pulse, the temperature of the tumor afferent blood is brought to the measured temperature, and during the application of alcohol to the skin, the skin above the tumor is brought to a low temperature. Upon substitution of experimentally obtained values for the various parameters and appropriate heat-exchange terms, the coupled set of ordinary differential equations is solved by digital computer, with the use of a fourth-order Runge-Kutte method to calculate the temperature distribution in each compartment.

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

Harvard Medical School Continuing Education Program

The following courses are being offered by the Department of Radiology, Brigham and Women's Hospital, and the Department of Continuing Education, Harvard Medical School:

Clinical Nuclear Medicine: 1982—Sixth Annual Postgraduate Course; AMA Category I Credit 26 hours; William D. Kaplan, M.D., Program Director; course date April 21–24, 1982.

Ultrasound for Clinicians—Seventh Annual Postgraduate Course; AMA Category I Credit 20 hours; Jason C. Birnholz, M.D., Program Director; course date May 3–5, 1982.

Cardiac Angiography 1982: Diagnostic and Therapeutic Coronary Arteriography—Annual Postgraduate Course; AMA Category I Credit 28 hours; David C. Levin, M.D., Program Director; course date May 24–27, 1982.

For additional information please contact the Department of Continuing Education, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115 (telephone: 617-732-1525).

Aspirin Foundation of America

New Orleans, Louisiana, will be the site of this symposium to be held at the Tulane University School of Medicine on April 21–23, 1982. Participants will include 18 internationally recognized medical authorities who will take a new look at this versatile medication that continues to be cited in medical world literature for important new uses.

For additional information please contact Mr. Garrett Swenson, Chairman Symposium Committee, Aspirin Foundation of America, Inc., c/o American Home Products, 685 Third Avenue, New York, New York 10017 (telephone: 212-878-6150).

Cancer Management 1982

The Oncology Program of the University of Maryland School of Medicine and the American Cancer Society, Maryland Division, Inc., will present this course to be held at the Hyatt Regency, Baltimore, Maryland, on May 21–22, 1982.

For further information contact the Program of Continuing Education, University of Maryland School of Medicine, 10 South Pine Street, Baltimore, Maryland 21201 (telephone: 301-528-3956).

World Symposium on Asbestos

"Asbestos, Health, and Society" is the title of this symposium, sponsored by the Government of Canada, the Government of Quebec, and the Commission of the European Communities, to be held at the Sheraton Mt-Royal Hotel in Montreal, Canada, on May 24–27, 1982. The program has been designed to yield an exhaustive evaluation of the current asbestos situation, and to promote the free expression of the differing views held throughout the world on the subject.

For additional information please contact the Secretariat, World Symposium on Asbestos, 84 de Brésoles Street, Old Montreal, Quebec, Canada H2Y 1V5 (telephone: 514-845-6165; telex 05-24245).

First International Symposium on the Endocrine Lung in Health and Disease

The Veterans Administration Medical Center and the National Cancer Institute, in conjunction with George Washington University Medical Center, will conduct this conference to be held at the Hyatt Regency Capitol Hill hotel in Washington, D.C., on June 2–4, 1982. A panel of invited speakers will discuss the pulmonary endocrine cell, including anatomy, embryology, histochemistry, and the pathophysiology of its peptide products. Special sessions will be devoted to pulmonary endocrine tumors (small cell cancer and carcinoid).

For further information please contact Mr. Peter Petrossian, George Washington University Medical Center, Office of Continuing Medical Education, 2300 "K" Street, N.W., Washington, D.C. 20037 (telephone: 202-676-4285).

World Congress of Gastroenterology, Digestive Endoscopy, and Colo-Proctology

Stockholm, Sweden, will be the site of this meeting to be held on June 13–19, 1982. All information can be obtained from Stockholm Convention Bureau, Jakobs Torg 3, S-111 52 Stockholm, Sweden.

Annual Course in Advanced Immunology

The American Association of Immunologists will sponsor this course entitled "Regulatory Elements of the Immune System" to be held at Duke University, Durham, North Carolina, on June 15–24, 1982. Rapid advancements have led to an increased understanding of immune regulation and its application to the manipulation of responsiveness. This course will delve into these advances in immunobiology, immunogenetics, and molecular and clinical immunology. Topics will include immunoglobulin and MHC gene organization and control, regulation by interleukins, T and B cell clones and hybrids, effector mechanisms, and immunologic analysis and intervention in human disease.

To apply for the course, please submit a letter documenting your background in immunology and stating your reasons for wishing to attend, as well as current research/teaching activities and a brief c.v., no later than April 10, 1982, to: Dr. David W. Scott, AAI Course, Box 3010, Division of Immunology, Duke University Medical Center, Durham, North Carolina 27710.

First Conference on Radioprotectors and Anticarcinogens

This conference, sponsored by the National Bureau of Standards, National Cancer Institute, Federal Emergency Management Agency, Radiation Research Society, National Council on Radiation Protection and Measurements, and Commission of European Communities, will be held at the National Bureau of Standards, Gaithersburg, Maryland, on June 21–24, 1982. The conference will address the chemical, biochemical, and biological aspects of the effects of ionizing radiation and of chemical carcinogens and agents capable of altering these effects. The program will focus on the protection against acute (radiation sickness and lethality) and long-range (mutation and carcinogenesis) effects. In particular, it will address the relationships between protection from ionizing radiation and chemical carcinogens, pursue correlations of free-radical chemistry and the observed biological phenomena, and, finally, attempt to establish immunological, physiological, and nutritional criteria for "intrinsic resistance" toward radiation and chemical insults.

The conference will consist of 6 half-day sessions with 5–6 invited speakers per session, a panel discussion, and a poster session for contributed papers. Abstracts for posters will be required by May 1, 1982. For further information contact Ms. Kathy C. Stang, Materials Building B-348, National Bureau of Standards, Washington, D.C. 20234 (telephone: 301-921-3295 or Dr. M. G. Simic, 301-921-2374).

Design and Analysis of Scientific Experiments

The Massachusetts Institute of Technology will offer this one-week elementary course on July 12–17, 1982. Applications will be made to the physical, chemical, biological, medical, engineering, and industrial sciences, and to experimentation in psychology and economics. The course will be taught by Professors Harold Freeman and Paul Berger.

Further particulars may be obtained in writing to the Director of Summer Session, Room E19-356, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139.

Veterinary Cancer Society

The executive committee of the Veterinary Cancer Society invites veterinarians and other health-related professionals to join our organization. The Veterinary Cancer Society is a non-profit educational organization whose objectives include promoting: 1) high standards of diagnosis, treatment, and prevention of animal cancers; 2) interdisciplinary research in neoplastic diseases of animals; 3) collection and dissemination of information about animal neoplasms; and 4) the design, implementation, and evaluation of studies of animal neoplasms, including cooperative clinical trials.

The Veterinary Cancer Society meets at least twice annually and publishes a quarterly newsletter. For the last two years we have cosponsored symposiums on clinical trial/protocol design at Purdue University.

Annual dues are currently $20. Interested persons should obtain an application for membership from Dr. Darryl N. Biery, Treasurer, Veterinary Cancer Society, University of Pennsylvania, School of Veterinary Medicine, Philadelphia, Pennsylvania 19104.

U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES Public Health Service National Institutes of Health

HE 20.3161:

The cover illustration depicts the pedigrees of 13 families showing carotid body tumors (*see* paper by Parry et al. on pages 573–578).

JNCI

Journal of the National
Cancer Institute

April 1982
Volume 68
Number 4

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $6.00. Subscription price for two volumes per year in the United States, $65.00; foreign, $81.25. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20016.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20016.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols: *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40: 2083–2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221–245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs.* Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Medicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3–10/Ann Intern Med 1979;90:95–99/Br Med J 1979;1:532–535/ or Lancet 1979;1:428–430).

ABSTRACT—There was no overall relationship between a prior history of oral contraceptive (OC) use and the development of melanoma among 141 cases of nonfatal malignant melanoma and 2,820 age-matched controls drawn from respondents to a large postal survey of registered U.S. nurses; crude relative risk (RR) was 0.93 and 95% confidence limits (CL) were between 0.64 and 1.36. Adjustment for a number of additional variables did not alter this estimate materially. Duration of OC use and interval since first use were similarly unrelated to the occurrence of melanoma. For women diagnosed before age 40, there was a crude positive association of "ever" use of OC and melanoma (RR=1.78; 95% CL, 1.11–2.86). However, adjustment for geography and other variables diminished this association and rendered it statistically not significant (RR=1.43; 95% CL, 0.83–2.46). These data do not support the hypothesis that OC use is an independent risk factor for melanoma.—JNCI 1982; 68:537–539.

The possibility that OC use causes melanoma was first raised in a case report in 1968 (*1*). The findings of one prospective study of small sample size have provided some support for this correlation (*2*). Moreover, the hypothesis is consistent with existing biological knowledge. Specifically, OC use alters skin pigmentation in some women (*3*) and estrogen receptors have been identified in human melanomas (*4, 5*), whereas injection of estrogen and progesterone into guinea pigs has been shown to increase melanocyte numbers and skin melanin content (6). This study examines the relationship of OC use with melanoma in case–control data.

METHODS

In 1976, questionnaires were mailed to all married female registered nurses 30–55 years of age who resided in 11 of the larger U.S. states and who were listed in the 1972 register of the American Nurses' Association. Of 172,413 nurses receiving questionnaires, 121,964 completed and returned them. Further details are given in a previous publication (*7*). Information was obtained about a history of any previous diagnosis of cancer, including specific type, and about current and past use of OC, including dates of starting and stopping each interval of use.

Among the respondents 142 reported a diagnosis of malignant or unspecified melanoma or malignant mole of the skin, generally without noting location, subsequent to 1960, when OC were first marketed commercially in the United States (*8*). A pathology report or a pathology note in the discharge summary was obtained for 85 cases, and the diagnosis was confirmed for 84 of them; the one uncertain diagnosis was excluded from all analyses. Thus the analyses were based on 141 cases of which 30 were described as the superficial spreading type, 1 as nodular, and the remainder as simply melanoma. For each case, 20 controls matched on year of birth were selected at random from the total group of respondents. OC use was defined as use at least 1 month prior to the date of diagnosis for each case, which was also used as the index date for her 20 controls; duration of use was the sum of all intervals of use prior to diagnosis. Where pertinent, additional variables were similarly related to date of diagnosis.

The strength of the association between OC use and melanoma was assessed by computing RR. These RR were adjusted for potential confounding variables by a multiple logistic regression procedure (*9*). For each RR, 95% CL were obtained (*10*); for the logit estimates, $CL=e^{(\ln RR \pm 1.96\ SE)}$ was applied.

RESULTS

There was no overall association between prior use of OC and a diagnosis of melanoma (RR=0.93; 95% CL, 0.64–1.36) (table 1). A logistic regression analysis adjusting for age at diagnosis, state of residence (grouped as Northern, Southern, or Central States), parity, age at first pregnancy, height, and prior hair dye use did not materially change this estimate for "ever" use of OC (RR=0.82; 95% CL, 0.53–1.27). These variables were included in the analyses because they either influence a woman's hormonal status (parity, age at first pregnancy) or demonstrated some association with a diagnosis of melanoma in crude analyses of these data. No information was collected on skin color.

The only significant predictor of increased risk in the logistic analysis was geography: The RR for those living in Southern States (Florida, Texas, and California) was 2.73 (1.63–4.59) compared with dwellers in Central States (New Jersey, Maryland, Pennsylvania, and Ohio). There was a

TABLE 1.—*Crude and adjusted RR of melanoma among women who had, at any time, used OC, compared with those who never used OC*

Age at diagnosis, yr	No. of exposed cases	Crude RR (95% CL)	Adjusted RR (95% CL)
All women	41	0.93 (0.64–1.36)	0.82 (0.53–1.27)
<40	29	1.78 (1.11–2.86)	1.43 (0.83–2.46)
40–49	12	0.45 (0.23–0.86)	0.37 (0.17–0.79)

lesser excess risk for residents of Northern States (Connecticut, Massachusetts, Michigan, and New York), RR=1.84 (1.13–3.01).

There was no significant excess risk with increasing duration of use of OC (table 2). Again, this result was not altered by adjustment for all additional variables combined in logistic regression analysis. Similar results were obtained when the interval since the first use of OC was considered, and no consistent trend was evident when duration and interval were considered together.

Age-specific RR estimates (tables 1 and 2) indicate positive crude relationships with melanoma for women diagnosed before age 40 for "ever" use of OC and for 2 years or more of use. However, as shown in the tables, multivariate adjustment diminished the magnitude of these associations and rendered them statistically not significant. Among this subgroup of younger women, the strongest relationship with melanoma was for those who had used OC for more than 2 years and had started OC use at least 10 years prior to diagnosis, yielding RR=2.95 (1.16–7.49), based on 5 exposed cases. Again, the association was reduced in a logistic analysis, yielding RR=2.31 (0.77–6.94). Corresponding deficits of exposed cases existed among women diagnosed after age 40. As shown in table 3, the OC–melanoma association was significantly greater in women less than or equal to 39 years of age compared with those 40 and older ($P<0.001$ (*11*).

Restricting analysis of the relationship between OC use and melanoma to the 84 pathologically confirmed cases produced results similar to those obtained with the use of the entire data set. However, the statistical significance of the OC–melanoma associations among those with diagnoses at young ages were diminished or eliminated due to the smaller sample size.

Current or recent OC use did not exhibit different relationships with melanoma risk from those reported above for "ever" use.

DISCUSSION

The results of this study do not lend support to the general hypothesis that OC use predisposes to the development of malignant melanoma, although the adjusted RR of 0.82 (95% CL, 0.53–1.27) is compatible with up to a 27% excess risk among "ever" users of OC. The marginally significant crude association between OC use and melanoma among women diagnosed at younger ages decreases in strength and is no longer significant when the effects of other variables are controlled. The CL are wide, and a positive relationship cannot be excluded with certainty, particularly when considering the excess risk among younger women. As always, however, results of subgroup analyses should be interpreted cautiously, especially in view of the corresponding diminished risk among older women. The substantial decreases in RR among the younger women after adjustment for a few factors suggest that they may be even further diminished if more precise information had been obtained for other potentially confounding variables. These variables would include actual sun exposure, for which geography may be a crude marker (*12*), the use of protective sun screens and clothing, and skin color (*13–16*). In addition, because the etiology of the disease is so poorly understood, it is possible that other unknown sources of confounding might also have been present.

The lack of specific information on skin color merits comment. With the presumption that all cases were white, if blacks formed a substantial proportion of the control group and had used OC more than whites, a spurious lowering of the estimated risk could have occurred. However, a survey of the membership of the American Nurses' Association in 1974 recorded only 3.4% as black (American Nurses' Association: Unpublished data). With the use of this as the best estimate of the proportion of controls who were black, and with the extreme assumption that all had used OC, the overall RR for whites is still less than 1.0.

Because the study was based on responses to a postal questionnaire, the results concern only nonfatal cases of melanoma. This situation could lead to bias only if the fatality rates were different among users and nonusers of OC. In that regard, there is some evidence that hormonal factors may influence prognosis (*17–18*). In addition, most melanomas fall into one of two distinct histologic types [superficial spreading and nodular melanoma (*19*)], which could have different causes. Because nodular lesions have a worse prognosis (*19*) and are therefore likely to be underrepresented in our data, an association between OC use and fatal melanoma cannot be dismissed on the basis of the present findings. Various other sources of bias might exist in

TABLE 2.—*Crude and adjusted RR of melanoma among women using OC for various durations, compared with those who never used OC*

Age at diagnosis, yr	Duration of use, mo	No. of exposed cases	Crude RR (95% CL)	Adjusted RR (95% CL)
All women	1–24	18	0.83 (0.50–1.39)	0.84 (0.47–1.49)
	25+	23	1.04 (0.65–1.66)	0.83 (0.47–1.46)
<40	1–24	12	1.36 (0.71–2.60)	1.21 (0.59–2.48)
	25+	17	2.29 (1.30–4.02)	1.73 (0.88–3.39)
40–49	1–24	6	0.49 (0.21–1.15)	0.49 (0.18–1.30)
	25+	6	0.42 (0.18–0.98)	0.29 (0.11–0.81)

TABLE 3.—*Estimated RR of melanoma among younger and older women who had used OC previously compared with those who never used OC*

Age at diagnosis, yr	OC	Cases	Controls	RR
<40	+	29	394	1.78
	−	46	1,114	
40–49	+	12	413	0.45
	−	37	573	

this study (*7, 20*), but they are unlikely to have influenced the present findings.

The etiology of malignant melanoma remains poorly understood. Recent reviews have had nothing explicit to say about the risk factors other than that sun exposure is probably implicated (*19, 21*), and only a few small analytical studies have been reported previously (*2, 13–15*). The current study does not provide support for the existence of a causal association between OC use and melanoma, but it does not definitely exclude such a relationship, particularly among younger women and for fatal disease. Neither the current investigation nor the only other analytical study of OC use and melanoma reported to date (*2*) has specific information about sun exposure. Concurrent information on both variables will be necessary to reach more definitive conclusions about the part OC use may play in the development of melanoma. In addition, as the importance of dietary factors in the etiology and prevention of many cancers is becoming increasingly obvious (*22–23*), data on food consumption should be gathered to broaden our understanding of the causal pathways for melanoma and to allow study of interrelationships between OC use, diet, and melanoma.

In summary, the present study does not confirm previous suggestions of an overall association between OC use and melanoma, although it does raise the possibility that use of OC at younger ages for long periods may predispose to the development of this cancer. Further analytic studies of this relationship are needed that pay particular attention to histologic type of tumor (*19, 24*) and possibly to tumor site (*2*), as well as to potential confounding variables, especially to details of sun exposure and diet.

5-Fluorouracil, 1,3-Bis(2-chloroethyl)-1-nitrosourea, and 1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea: Effect on the Human Granulopoietic System[1,2,3]

Hans-Peter Lohrmann,[4] Karin A. Lepp,[4] *and* Wolfgang Schreml[4,5]

ABSTRACT—The reaction pattern of the normal (nonleukemic) human granulopoietic system to single-agent treatment with 5-fluorouracil (FUra) and to a combination of FUra with two nitrosoureas, 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU) and 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea (MeCCNU), was studied serially by morphologic and in vitro culture methods. The granulopoietic toxicity of FUra was acute and rapidly (by day 21) reversible. In contrast, the toxicity of the combination regimens was long lasting. Evidence exists that an early toxicity (that of FUra) and a delayed toxicity (that of the nitrosourea) were overlapping. Toxicity of BCNU and MeCCNU was most pronounced at the level of in vitro colony-forming units of the granulopoietic system (G-CFU$_C$). G-CFU$_C$ compartments of bone marrow and peripheral blood continued to be reduced in size at the time of recovery of the peripheral blood granulocyte count from nitrosourea-induced toxicity. This finding may be responsible for the cumulative toxicity to the human hematopoietic system that frequently has been observed after repeated administration of nitrosourea compounds.—JNCI 1982; 68:541–547.

Toxicity to the hematopoietic cell-renewal systems is a typical side effect of most cytotoxic drugs. For many of these drugs, this toxicity determines maximal tolerated doses and/or minimal time intervals between successive courses. For the majority of alkylating agents (with the exception of busulfan), antimetabolites, vinca alkaloids, and cytotoxic antibiotics, the cytotoxic drug-induced bone marrow failure is of short duration (*1*). However, the toxicity produced by the nitrosoureas does not fit this general pattern. A characteristic feature of the nitrosoureas is the long duration of hematotoxicity that follows single or short-term administration both in experimental animals (*2–12*) and humans (*13–20*). Studies in animal models have defined the reactions of the granulopoietic system at its different levels to nitrosoureas; similar data are not available for humans.

The increasing use of nitrosourea compounds in the treatment of human malignant diseases (*21, 22*) prompted us to study the effect of BCNU and MeCCNU on the human granulopoietic system. For clinical reasons, both drugs were administered in combination with FUra; therefore, the effect of FUra monotherapy on the human granulopoietic system also was studied. Our findings demonstrated that nitrosoureas depress the G-CFU$_c$ for a prolonged period of time. The observation that peripheral blood SNG recover in the presence of a continued depletion of the G-CFU$_c$ compartment may explain the cumulative toxicity frequently observed after repeated administration of nitrosoureas.

MATERIALS AND METHODS

Patients and treatment.—Twelve patients (ages 29–70 yr; median age, 64 yr) were treated with FUra for metastatic gastrointestinal tumors. The drug was given iv at a dose of 12.5 mg/kg body weight on each of 5 successive days.

As part of a clinical study on the effect of adjuvant chemotherapy for gastric cancer, 9 patients (ages 40–68 yr; median age, 62 yr) were treated with a combination of FUra (10 mg/kg, iv, on days 1–5) plus BCNU (40 mg/m^2 body surface area, iv, on days 1–5) after gastrectomy.

Twelve patients (ages 24–68 yr; median age, 55 yr) were treated with FUra (10 mg/kg, iv, on days 1–5), vincristine (1.4 mg/m^2, iv, on day 1), plus MeCCNU (175 mg/m^2, orally, on day 1) for various metastatic gastrointestinal tumors. MeCCNU was provided by the Investigational Drug Branch, Division of Cancer Treatment, National Cancer Institute, Bethesda, Md.

None of the patients had been pretreated with cytotoxic agents or radiotherapy before this study, and none had evidence of bone metastases as determined by X-rays, scintigrafy, and marrow aspirates. The patients had given informed consent, and they were aware that participation in the hematologic investigation program was not a prerequisite for treatment and that their participation could be stopped at any time during treatment.

Hematologic studies.—Bone marrow was aspirated from the posterior iliac crest after local anesthesia on day 0 (before drug administration) and, whenever possible, weekly thereafter during the first treatment course. The marrow (4–5 ml) was aspirated into a syringe containing 1 ml of sterile isotonic disodium EDTA solution. For preparation of marrow smears, approximately 1 ml of marrow was aspirated into a second EDTA-coated syringe after the position of the aspiration needle had been changed. Most aspirations were done by one of two physicians, and attempts were made to standardize as much as possible the variables of the aspiration technique (site and depth of aspiration, suction force,

aspiration volume). Samples of venous peripheral blood were collected in heparinized syringes before each bone marrow aspiration.

The techniques of preparation of bone marrow and peripheral blood for G-CFU$_c$ cultures and the details of the culture technique were described in (*23, 24*). A single-layer agar (0.3%) culture was used; as a source of colony stimulating activity, 10% of human placenta-conditioned medium (*23*) was added. Cultures were set up in the presence of 15% fetal calf serum and were incubated for 10 days at 5% CO_2 in air in a humidified incubator. Colonies were defined as cell aggregates of more than 50 cells.

The details of the [^{3}H]thymidine suicide technique, performed to assess the proliferative activity of bone marrow G-CFU$_c$ after cytotoxic agent administration, were previously described (*25*). The "suicide fraction" indicates the percentage G-CFU$_c$ loss after in vitro incubation with radioactive [^{3}H]thymidine of high specific activity. The greater the suicide fraction, the greater was the proliferative activity of the G-CFU$_c$ population under study.

Morphologic evaluation of bone marrow smears.—Bone marrow differentials were obtained by differentiating at least 300 well-preserved bone marrow cells in at least 10 different parts of technically well-prepared Pappenheim-stained bone marrow smears. Erythrocyte:granulocyte ratios were calculated from the number of cells in the erythroid and granulocytic series. The proliferative granulocytic pool was defined as myeloblasts to myelocytes, and the maturing granulocytic pool as megamyelocytes to segmented neutrophils (*26*).

Estimation of bone marrow compartment sizes.—Any study of the effect of cytotoxic agents on human bone marrow is limited by the lack of methods to determine repeatedly at short intervals the human bone marrow compartment sizes. Both in vitro progenitor cell culture data and bone marrow differential counts provide relative data. Because marrow composition and bone marrow cellularity change at the same time after chemotherapy, such relative data provide rather limited information on the cytotoxic drug-induced changes of the bone marrow. This information is comparable to that provided by peripheral blood differential counts without knowledge of the absolute leukocyte counts.

In an effort to circumvent this methodologic problem, we assessed the usefulness of the bone marrow cell concentration of marrow aspirates, obtained under standardized conditions, as an index of the cellularity of human bone marrow. Although bone marrow aspirates do not always reflect accurately the marrow cellularity, some investigators have found the method to be of some value (*27, 28*). From our own experience with a rather large population of patients treated for primary breast cancer with adjuvant chemotherapy (*24*), we found the median bone marrow cell concentration of standard aspirates (corrected for the admixture of peripheral blood nucleated cells) to be a useful index of cytotoxic drug-induced changes in marrow cellularity (*29*). In the same patients, calculation of marrow cellularity from methyacrylate-imbedded sections of marrow spicules yielded comparable data (*30*). Thus we considered the bone marrow cell concentration of the aspirates times the relative number of cells in the marrow compartment under study as an index value for the compartment's size. These values were normalized, the pretreatment value being 100%. This method cannot provide exact data; however, from our experience we believe the time course of these compartment indices to be considerably more meaningful than that obtained only from the relative numbers of a given cell type.

Statistical anaylsis.—Statistical analysis was done by means of a program for a desk computer (model 983A; Hewlett-Packard Co., Palo Alto, Calif.) and the two-sided Mann-Whitney *U*-test.

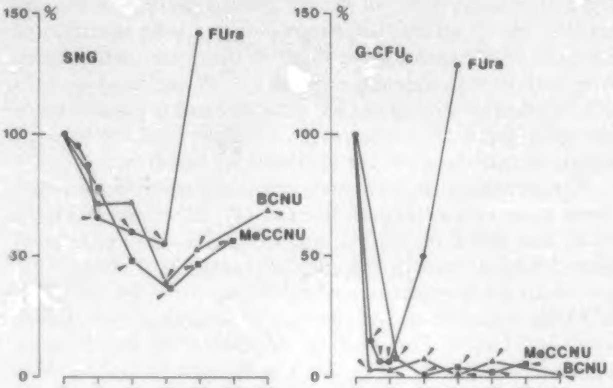
RESULTS

Peripheral Blood SNG

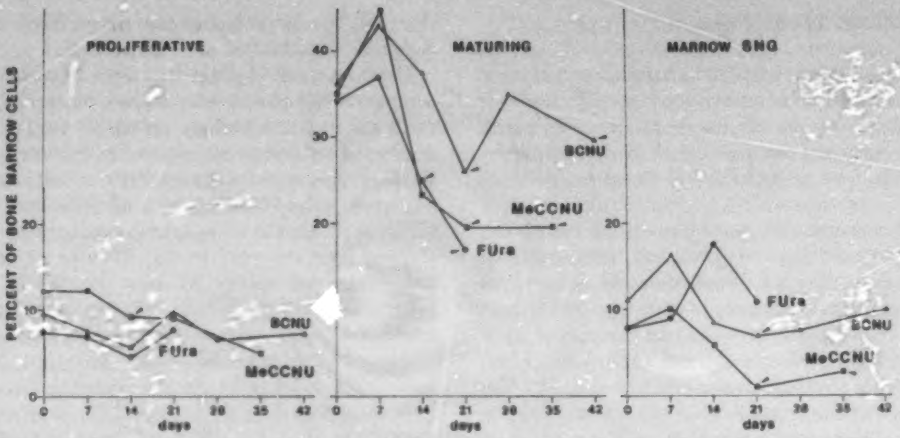
Text-figure 1 shows the longitudinal changes of peripheral blood SNG after administration of the three drug regimens. Monotherapy with FUra caused a decline in blood granulocyte counts after day 5; nadirs were reached on day 21, and recovery to supranormal values were reached by day 28. After treatment with both nitrosourea-containing drug regimens, peripheral blood SNG similarly reached nadirs on day 21; however, in contrast to monotherapy with FUra, granulocyte counts recovered only gradually thereafter, and pretreatment values were not reached by day 35 and day 42 for MeCCNU and BCNU, respectively.

Peripheral Blood G-CFU$_c$

Chemotherapy-induced changes of the peripheral blood G-CFU$_c$ pool size (G-CFU$_c$/liter) are included in text-figure 1. After administration of FUra, a transient decrease occurred in the peripheral blood G-CFU$_c$ pool size; lowest values were reached between days 5 and 7 after treatment initiation. By day 14, recovery was apparent, and repletion of the peripheral blood G-CFU$_c$ pool was completed by day

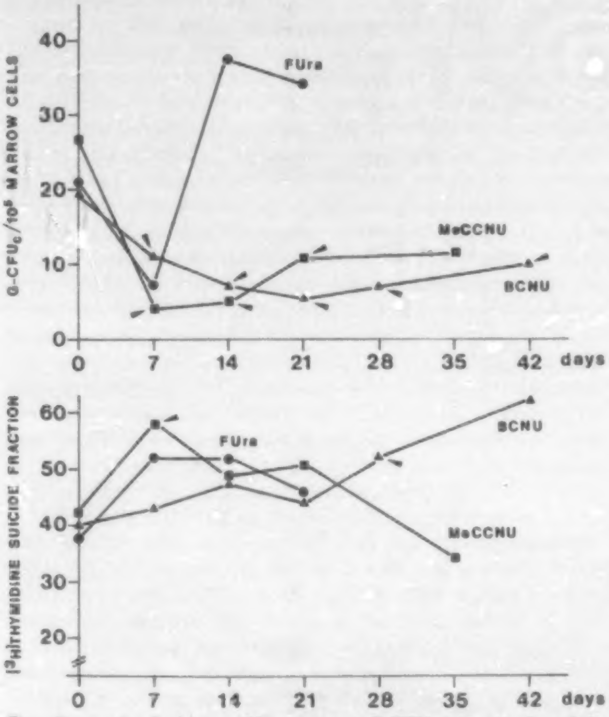


TEXT-FIGURE 1.—Time course of peripheral blood SNG/µl (*left panel*) and peripheral blood G-CFU$_c$/1 (*right panel*) after single-agent therapy with FUra (days 1–5), BCNU (days 1–5) + FUra (days 1–5), and MeCCNU (day 1) + FUra (days 1–5) + vincristine (day 1). Individual values at the different time points were normalized, the pretreatment value being 100%. Median values at the different time points are given. *Arrows* indicate values significantly ($P<0.05$) different from pretreatment values.



TEXT-FIGURE 2.—Bone marrow differential counts (median values) after treatment with FUra, BCNU + FUra, or MeCCNU + FUra + vincristine. *Proliferative*: proliferating granulocytic compartment (myeloblasts to myelocytes). *Maturing*: maturing granulocytic compartment (metamyelocytes to segmented neutrophils). *Marrow SNG*: segmented neutrophils. For further explanation, *see* legend to text-fig. 1.

21. After MeCCNU therapy, decreases in the peripheral blood G-CFU$_c$ pool size to near-zero values were recorded on days 14, 21, and 28 after chemotherapy; by day 35, there was no G-CFU$_c$ pool size recovery. Similarly, treatment with BCNU was followed by the almost complete disappearance of G-CFU$_c$ from the peripheral blood after day 3. As late as 42 days after treatment, no signs of recovery of the peripheral blood G-CFU$_c$ pool were evident.



TEXT-FIGURE 3.—Incidence of bone marrow G-CFU$_c$ (*upper panel*) and the [^{3}H]thymidine suicide fraction of marrow G-CFU$_c$ (*lower panel*) after treatment with FUra, BCNU + FUra, or MeCCNU + FUra + vincristine. Median values at the different time points are given. *Arrows* indicate values significantly ($P<0.05$) different from pretreatment values.

Bone Marrow Differentials

The percentages of cells in the proliferating and maturing granulocytic pool and the percentages of bone marrow granulocytes, as derived from bone marrow differential counts, for the three treatment regimens are included in text-figure 2. The percentages of cells in the different granulopoietic compartments reflect not only size changes of these pools but also changes in the nongranulopoietic compartments (e.g., changes within the erythropoietic compartments). Therefore, no clear pattern can be derived from the data. Shortly after chemotherapy, however, a decrease apparently occurs in the relative number of cells in the proliferating granulocytic pool, concomitant with a relative increase of cells in the maturing granulocytic pool.

Incidence and Proliferative Activity of Bone Marrow G-CFU$_c$

Changes in the incidence of bone marrow G-CFU$_c$ (e.g., the number of G-CFU$_c$/10^5 bone marrow cells after administration of the three cytotoxic drug regimens) are shown in text-figure 3. After FUra monotherapy, a transient decrease occurred by day 7, with subsequent rebound to supranormal values by days 14 and 21. In contrast, the number of bone marrow G-CFU$_c$ remained considerably below pretreatment values after treatment with MeCCNU, and even more so after treatment with BCNU.

Included in text-figure 3 are the values for the [^{3}H]thymidine suicide fraction of bone marrow G-CFU$_c$ after cytotoxic drug treatment. After monotherapy with FUra, a small increase occurred in G-CFU$_c$ proliferative activity, but this increase was not statistically significant. Increased values for the proliferative activity of bone marrow G-CFU$_c$ after treatment with MeCCNU and BCNU were noted at some time points; again, these increases were not even marginally statistically significant. Because of the low absolute numbers of G-CFU$_c$ at these later time points after chemotherapy, statistical significance only can be expected when a clear-cut increase occurs in the proliferative activity.

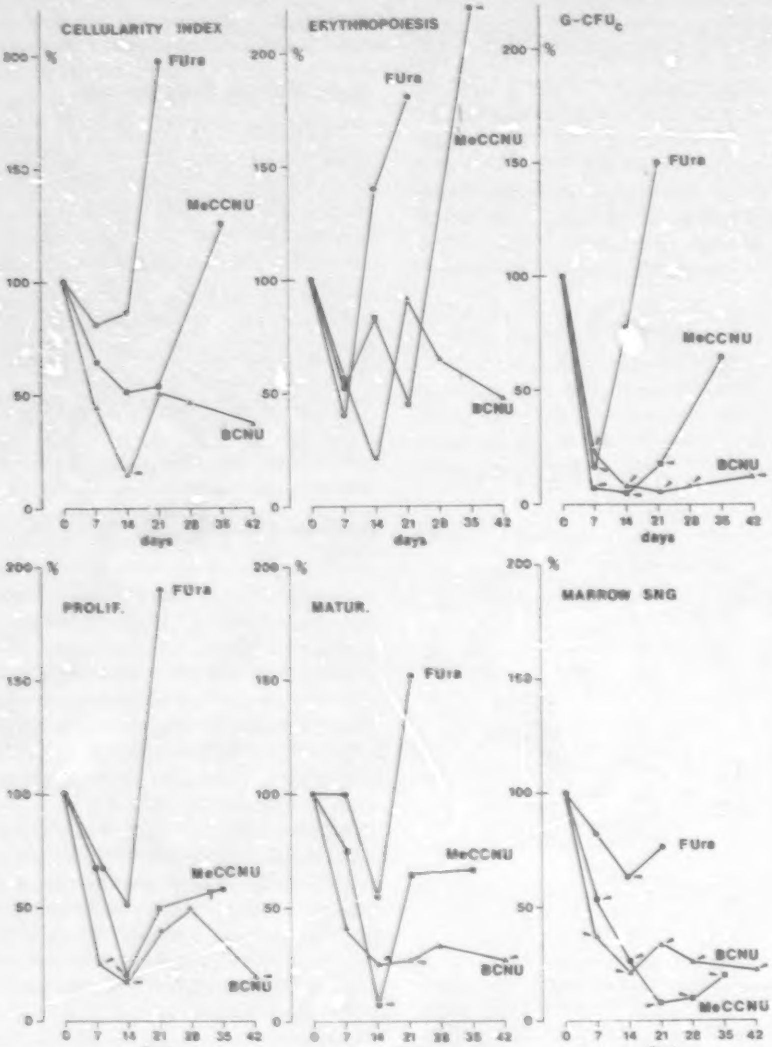
Bone Marrow Compartment Sizes

Text-figure 4 shows the normalized changes with time of the different granulopoietic compartment sizes of the bone marrow after administration of the three drug regimens. Also included is a longitudinal assessment of the cellularity changes and normalized erythroid cell numbers of bone marrow.

After FUra monotherapy, bone marrow cellularity changed little during the first 14 days, but it increased to supranormal values by day 21. Erythroid cells showed an early decrease (day 7) and increases in numbers by days 14 and 21. Among the different granulopoietic marrow compartments, the G-CFU$_c$ were greatly depleted by day 7 and returned to somewhat supranormal values by day 21. The compartment of maturing granulocytic cells was smallest by day 14; by day 21, bone marrow SNG continued to be reduced in numbers.

Bone marrow cellularity after MeCCNU therapy was considerably below pretreatment values through day 21 but returned to pretreatment values by day 35. The number of erythroid cells showed two nadirs by days 7 and 21, respectively, but it returned to highly supranormal values by day 35. Among the granulopoietic compartments, the pool of G-CFU$_c$ was almost completely depleted by days 7 and 14, showed little recovery by day 21, and was still considerably below normal values by day 35. While the number of proliferating granulocytic cells was lowest on day 14, the number of bone marrow SNG reached its nadir by day 21.

After BCNU therapy, bone marrow cellularity reached low values on day 14, increased somewhat by day 21, but decreased again on days 28 and 42. Erythroid marrow cells



TEXT-FIGURE 4.—Bone marrow cellularity and bone marrow compartment sizes after treatment with FUra, BCNU + FUra, and MeCCNU + FUra + vincristine. Individual values were computed as described in "Materials and Methods" and normalized to the pretreatment value. Median values of th 3 treatment groups at the different time points are given. *Arrows* indicate values significantly different ($P<0.05$) from pretreatment values.

showed a similar reaction to the chemotherapy. All of the different granulopoietic compartments had decreased by days 7 and 14. By day 21, an abortive rise in the granulocytic proliferative and maturing pools was noted, followed by a second gradual decline. Definitive signs of recovery were not apparent as late as day 42 in any of the hematopoietic marrow compartments. At that time, the extent of recovery was smaller in the G-CFU$_c$ compartment than in the more mature granulocytic compartments.

DISCUSSION

The purpose of this study was to delineate the reaction pattern of a "normal" human granulopoietic system to three cytotoxic drug regimens, two of which contained nitrosourea compounds. However, the rather wide range of pretreatment values and the considerable variability of the changes observed in individual patients after chemotherapy raised the question whether these patients' granulopoietic systems were indeed normal. Disturbance of the hematopoietic system by tumors has been documented both clinically (*31*) and experimentally (*32–34*). Thus we cannot rule out that at least in some of the patients studied, the granulopoietic system was not in an undisturbed state. Nevertheless, the present study may reasonably well indicate the reaction pattern of the human granulopoietic system to the chemotherapy administered. To present the data in the most meaningful way, we chose to present the median rather than the mean values, thus correcting for some of the inhomogeneity in the patient populations under study.

Some of the variables that determine the toxicity of cytotoxic drugs on the granulopoietic system are well known: The dose of the drug is a major variable, but single doses act differently from repeated or split doses; similarly, drug combinations may exert toxicity different from that of the various components (*1*). Such variables may be studied easily in experimental animals. However, studies in humans only can be performed in the framework of an established or experimental treatment protocol, which sometimes may severely limit interpretation of the data. The value of such data lies in the fact that they refer to clinically relevant treatment schedules. For these reasons, the nitrosourea compounds were not given as single agents in the present study but rather in combination with a 5-day schedule of FUra. Also, a single dose of vincristine was added to the combination of FUra and MeCCNU. Thus the present study posed difficulties in defining the direct contribution of each of these cytotoxic drugs to the observed overall hematopoietic toxicity of the combination schedules.

The contribution of vincristine to the granulopoietic toxicity may be estimated from clinical and experimental observations. Vincristine is known for its low hematopoietic toxicity in humans. This is also true at the stem cell level in animal experiments (*35, 36*), and the same animal studies documented rapid hematopoietic recovery from vincristine-induced damage. Therefore, the conclusion is justified that vincristine contributed little if any to the early granulopoietic toxicity observed after treatment with a combination of vincristine, FUra, and MeCCNU, and that vincristine did not contribute to the late toxicity that occurred with this treatment schedule.

The extent and duration of the marrow toxicity exerted by the nitrosoureas alone may result from the differences in reaction pattern after FUra single-agent therapy and from that after FUra in combination with one of the nitrosoureas. A rather comprehensive picture of the cytotoxic drug-induced changes of the human granulopoietic system after administration of the three drug regimens may be drawn from the morphological differentiation of bone marrow and peripheral blood nucleated cells together with the culture of G-CFU$_c$. Our direct experimental data (text-fig. 1–3), and even more the results of our attempt at quantification of the size changes of the marrow compartments (text-fig. 4), indicate that granulopoietic toxicity is of immediate onset and of long duration after exposure to a combination of a 5-day schedule of FUra with either one of the two nitrosoureas (BCNU or MeCCNU). From comparison of this finding with the toxicity observed after single-agent therapy with FUra (repeated on 5 successive days), FUra apparently is responsible for part or all of the initial toxicity (days 0–21) observed after administration of the drug combinations. Our data do not permit us to exclude the possibility of a contribution from BCNU or MeCCNU to this initial toxicity. However, to ascertain whether such a contribution is involved, similar studies have to be performed after treatment with BCNU or MeCCNU alone. Our findings do permit us to attribute the delayed and long-lasting granulopoietic toxicity of the combination chemotherapy regimens solely to BCNU or MeCCNU. The abortive granulopoietic recovery noted on day 21 after treatment with FUra plus BCNU (text fig. 4) may reflect the overlap of the early FUra-induced toxicity and the delayed toxicity of the nitrosourea compound.

Our study demonstrated that the granulopoietic system depression is longer lasting after BCNU than after MeCCNU. However, this is not necessarily due to different properties of the two drugs, though BCNU may affect the cell cycle kinetics longer than does MeCCNU (*37, 38*). We gave MeCCNU as a single dose on day 1, whereas we gave BCNU in divided doses for 5 consecutive days. Animal studies on the changes with time in the hematopoietic stem cell compartments have been reported only after single doses of nitrosoureas (*2, 5, 8, 11, 12*) but not after repeated exposure to one of these compounds. Thus we can only speculate that greater damage to hematopoietic stem cells may result from split doses than from a single dose of BCNU.

Delayed hematopoietic toxicity of nitrosoureas has been reported in many experimental and clinical studies. Delayed recovery of pluripotent stem cells after nitrosourea exposure has been documented in experimental animals (*2, 8, 11, 12*). In mice, delayed recovery was accompanied by a low proliferative activity in those stem cells surviving BCNU treatment (*8*). The pattern of depletion and repletion of bone marrow G-CFU$_c$ appears to vary with the different species. Return of the G-CFU$_c$ compartment size to pretreatment values was reported to occur within 6 days in mice (*11, 12*), but normalization of the G-CFU$_c$ compartment in rats was seen only by day 21 (*5*). These and other data (*39, 40*) suggest a preferential kill of pluripotent stem cells by nitrosoureas. Bone marrow cellularity remained depressed for a prolonged period of time after nitrosoureas in both mice (*8, 10*) and rats (*5*). The duration of nitrosourea-induced peripheral blood granulocytopenia may be dose-dependent (*3*). After treatment with methylnitrosourea (*10*), a second long-lasting neutropenia was observed after an initial short-lasting recovery of peripheral blood neutrophil counts. In humans, delayed leukopenia and granulocytopenia are well-known characteristic side effects of exposure to nitrosoureas (*13–20*); these effects were corroborated in the present study.

The causes of the delayed and long-lasting hematopoietic toxicity after nitrosourea exposure are a matter of discussion. Nitrosoureas preferentially kill pluripotent stem cells. Evidence exists that nitrosoureas preferentially damage the earliest pluripotent stem cells that are endowed with the greatest potential for proliferation and self-replication (*39, 40*). Considerable time (which is determined by the proliferation kinetics of the granulocytic system) is required until the damage proceeds from the early stem cell level to the granulocyte compartments of bone marrow and blood. Because granulopoietic regeneration originates from pluripotent stem cells, their preferential damage may be responsible for the long duration of the granulopoietic toxicity caused by nitrosoureas.

Finally, nitrosoureas have been reported to induce a long-lasting reduction of the growth fraction of a proliferating cell population (*41*). This observation may provide an additional explanation for the long time required for hematopoietic reconstitution after nitrosourea treatment. It may also explain the failure of murine pluripotent hematopoietic stem cells (*8*) and human G-CFU$_c$ (text-fig. 3) to increase their proliferative activity early after administration of nitrosoureas to an extent similar to that reported after exposure to most other cytotoxic agents. The existence of long-lived metabolites has been suggested as a possible cause of the delayed hematopoietic toxicity of nitrosoureas (*22*). However, bone marrow transplanted within a few days after nitrosourea administration engrafts without any problems both in laboratory animals (*8, 42*) and humans (*43, 44*). This, in our opinion, refutes the hypothesis that the long-lived cytotoxic metabolites of nitrosoureas are responsible for their delayed hematotoxicity.

Regenerative rebound of bone marrow and peripheral blood G-CFU$_c$ frequently occurs during granulopoietic regeneration from cytotoxic drugs such as cyclophosphamide or methotrexate, particularly if the preceding cytotoxic drug-induced marrow hypoplasia was severe (*24, 45, 46*). No such rebound of bone marrow or peripheral blood G-CFU$_c$ occurred after exposure to the nitrosoureas. [We have also observed (unpublished data) that no rebound of G-CFU$_c$ occurred after repeated courses of nitrosoureas.] The failure of G-CFU$_c$ to regenerate with a rebound lends further support to the above suggestion that the proliferative activity of hematopoietic stem cells remains impaired over a prolonged period after exposure to nitrosoureas.

In clinical practice, the return of peripheral blood SNG from cytotoxic drug-induced depression toward normal is generally and tacitly assumed to indicate return of the granulopoietic compartments toward normal. We have previously demonstrated this assumption to be correct after cyclophosphamide–adriamycin "standard dose" combination chemotherapy (*24*), high-dose cyclophosphamide treatment (*45*), and high-dose methotrexate followed by citrovorum factor rescue (*46*). The present study indicates that recovery of human peripheral blood SNG counts occurs after nitrosourea treatment in spite of the continued depletion of the G-CFU$_c$ pool. A hypothetical explanation for this discrepancy may be a more rapid transit of cells through the depleted G-CFU$_c$ compartment. The slight increase in the proliferative activity of bone marrow G-CFU$_c$ at the time of peripheral blood SNG recovery after BCNU treatment (text-fig. 1, 3) is compatible with this interpretation. Granulocyte production may thus return to near-normal levels, while the progenitor cell compartment remains well below normal size. Furthermore, newly formed SNG apparently are released rapidly into the circulating blood rather than being retained in the bone marrow (text-fig. 2). This mechanism allows maintenance of near-normal peripheral blood SNG concentrations at the expense of a reduced bone marrow granulocyte storage pool.

It is well established clinical practice to readminister the nitrosourea as soon as the peripheral blood SNG count has returned to a normal level. However, repeated administration frequently has been observed to lead to cumulative toxicity (*16, 19, 20*). Our data allow a better understanding of this phenomenon: Apparently, in spite of the return of the peripheral blood SNG count to normal, a repeated nitrosourea dose will exert its toxicity on a G-CFU$_c$ pool that is still reduced in size. Conceivably, as in animal studies, the human pluripotent stem cell pool (at this time not accessible for quantiative analysis) undergoes changes that parallel those of the G-CFU$_c$ compartment. Thus the quantitative damage to the stem cell pool(s) will be greater after a second or third nitrosourea dose than after the first one. In addition, repeated exposure to nitrosoureas may lead to qualitative defects in hematopoietic stem cells. The repeated damage exerted by the drugs to the early pluripotent stem cells may lead to cumulative loss of proliferative capacity of the pluripotent stem cell compartment (*35*), curtailing this compartment's capacity to fulfill the demand for increased stem cell output into the hematopoietic cell lines during hematopoietic regeneration from nitrosourea-induced damage.

T_G Cell Involvement in the Leukocyte Adherence Inhibition Phenomenon[1,2,3,4]

S. G. Taylor IV,[5] Patricia C. Saffold,[5] Donald P. Braun,[5] and Jules E. Harris[5,6]

ABSTRACT—Peripheral blood mononuclear cells (PBMC), T-cells, non-T-cells, T_G cells, and T_M cells were tested for leukocyte adherence inhibition (LAI) reactivity to purified protein derivative (PPD) in normal human volunteers to determine the reactive cell subfractions. T-cells were separated by sheep red blood cell rosetting and T_M and T_G cells by rosetting with anti-ox red blood cell (ORBC) IgM- and IgG-treated ORBC. Fresh PBMC, T-cells, and T_G cells gave positive LAI reactivity to PPD in PPD-positive donors only. PBMC that had undergone 24-hour incubation or extensive washing, non-T-cells, and T_M cells were unreactive. All cell subfractions were negative in PPD-negative donors. Indirect LAI assay was performed on the spent media from overnight incubation of unstimulated PBMC and also following a 1-hour incubation of the various cell subfractions obtained from a PPD-reactive donor with PPD. Positive reactions, indicating the release of an LAI factor (LAIF), were obtained with the spent media and with the T-cell and T_G cell subfractions following PPD stimulation, whereas non-T-cell and T_M cell subfractions yielded no reactivity. Incubation of sensitized T-cells with PPD in the presence of cycloheximide and preincubation of T-cells for 24 hours with cycloheximide before PPD exposure failed to inhibit LAI reactivity. These data suggest that T-cells, specifically T_G cells, can release LAIF upon specific antigen stimulation with PPD, whereas non-T-cell and T_M cell subpopulations fail to respond to the same stimulus. LAIF may also be released into the culture media with prolonged (overnight) incubation in artificial media or with extensive washing. Inhibition of protein synthesis during antigen exposure or up to 24 hours before antigen exposure does not appear to inhibit LAI reactivity.—JNCI 1982; 68:549–554.

The LAI assay has been identified as a simple and reliable test of cell-mediated tumor immunity (*1*). Recent studies have correlated positive LAI activity with delayed hypersensitivity reactivity (*2*) and with positive migration inhibition (*3*). Using the hemacytometer glass slide method of the LAI assay, several investigators have identified T-lymphocytes as the active cell population involved in the assay (*4–6*). Substantial evidence has also evolved that the phenomenon of LAI is mediated by a soluble factor (LAIF) (*4, 5, 7*). Using soluble supernatants, Koppi et al. (*8*) have demonstrated the production of a soluble factor (LAIF) by T-lymphocytes and the capacity of this factor to inhibit adherence of normal, nonimmune T- and B-cells, granulocytes, and glass-adherent monocytes.

Others have demonstrated the active participation of macrophages and monocytes armed with cytophilic antibody as a reactive cell population (*9, 10*); these results derive from a different assay technique in which the tube method was used and tests were done for leukocyte nonadherence. Evidence is now substantial that this test is not comparable to the slide method in several respects in addition to the active cell population involved. For instance, evidence for mediation by a soluble factor is lacking (*10*). The tube LAI assay appears more sensitive to antigen concentration and, in patients with advanced disease, may convert to negative while the slide assay remains positive (*10–14*). Immune memory appears to fatigue earlier by the tube method (*11, 13*).

In our evaluation of the slide method of LAI, we have used PPD as an antigen source for testing normal adults. We have confirmed T-lymphocytes to be the active cell population and have further demonstrated the T-cell subset possessing Fc receptors to IgG (T_G cells) as that fraction having persistent LAI activity to this stimulus.

MATERIALS AND METHODS

Healthy volunteers were used as the source for mononuclear cells. PPD was obtained from Connaught Medical Research Laboratories, Toronto, Canada (batch #24) and was diluted with PBS to an initial concentration of 1,000 µg/ml.

Slide LAI assay.—A modification of the method as originally described by Halliday and Miller (*1*) and Halliday (*7*) was used. Cell subfractions were suspended in RPMI-1640 medium at a concentration of 2×10^7 cells/ml, and 0.1 ml was added to plastic tissue culture tubes (Falcon Plastics, Oxnard, Calif). The cells were diluted with 0.05 ml of RPMI-1640 for the controls or with 0.05 ml of PPD diluted to the appropriate concentration in RPMI-1640 for the test samples. To each tube was added 0.05 ml of diluted, heat-inactivated human serum to yield a final concentration of 1×10^7 cells/ml in RPMI-1640 with 25% human serum. The human serum was obtained from a single donor and had been previously tested to exclude nonspecific adherence inhibition activity. All tests were performed with quadru-

plicate samples. The samples were incubated at 37°C for 30 minutes with vigorous shaking every 10 minutes. A sample from each tube was placed on one hemacytometer slide and incubated in 5% CO_2 at 37°C with 100% humidity. After 60 minutes, eight predetermined 0.1×0.1-mm hemacytometer squares were counted in each slide. The cover slips were floated off, the slides were inverted twice in normal saline (once in each direction), a new cover slip was applied, and the same squares were counted again. The percentage cellular adherence (100×cells counted following washing/cells counted before washing) in each square was calculated and a mean plus or minus standard error determined for each sample. The significance of comparisons was determined by Student's *t*-test with $P<0.01$ indicating a positive reaction. All tubes were randomly coded before the first incubation by a nonparticipant in the experiment to prevent investigator bias. The samples were decoded at the time that statistical calculations were performed.

Indirect LAI assay.—PBMC subfractions were prepared as for the direct LAI test with the use of PPD-positive volunteers. These cell fractions were then incubated with or without PPD in the standard fashion except incubation time was increased to 60 minutes. The supernatants were removed and stored at 4°C overnight, with all samples subsequently tested on the same day. Aliquots of 0.1 ml supernatant were added to 0.1 ml of 2×10^6 PBMC collected from a PPD-negative donor and incubated at 37°C for 30 minutes with intermittent shaking. The cells were then placed on hemacytometer slides, and the LAI assay was performed in the usual manner (*8*).

Isolation of leukocyte subfractions.—Whole blood was aseptically collected in preservative-free heparinized tubes, diluted in HBSS, layered onto LSM, and centrifuged to obtain the PBMC layer. The PBMC have been found to contain between 5 and 15% contamination with granulocytes and monocytes (*15*). Residual red blood cells were lysed and platelets removed by slow centrifugation in 0.14 *M* NH_4Cl. Following two more washes, a portion of these cells was resuspended in HBSS, supplemented with 1% bovine serum albumin. We isolated T-cells by rosetting cells in the proportion of 5×10^6 cells (100 µl) with 300 µl of a 2% suspension of SRBC and 300 µl of heat-inactivated, SRBC-absorbed FCS. Tubes were incubated at 37°C for 5 minutes, centrifuged at 200×*g* for 5 minutes, and then incubated overnight at 4°C. The next day, pellets were gently resuspended, layered onto cold LSM, and centrifuged for 15 minutes at 1,600 rpm to obtain the T-cell-enriched and T-cell-depleted layers. The pellet that was enriched for T-cells was resuspended and washed in HBSS and then in 0.14 *M* NH_4Cl. Cells obtained by this method proved to be greater than 95% SRBC rosette-forming cells. Cells in the T-cell-depleted layer were not seen to rosette with sheep cells. A portion of these separate cell populations was tested for PPD reactivity in the LAI assay.

[a] All subfractions were positively isolated with the use of IgG- and IgM-bound ORBC except for T_M cells in experiment 3, which were taken from the T-cells remaining after separation of T_G cells.

[b] Results are mean percentage adherent cells of four assays ± the standard error.

The remaining T-lymphocyte-enriched cells were incubated overnight in RPMI-1640 medium supplemented with 20% FCS and 0.6% gentamicin in a humidified atmosphere of 5% CO_2 in air. The next day, cells bearing receptors for the Fc portion of IgG or IgM were isolated by the ORBC-rosetting techniques of Moretta et al. (*16, 17*) and Ferrarini et al. (*18*). Fresh ORBC were washed in PBS, and a 5% ORBC suspension was prepared in PBS. Subagglutinating concentrations of rabbit anti-ORBC IgG or IgM were mixed with the 5% ORBC suspension and incubated for 1.5 hours at 37°C in the case of IgG or for 45 minutes at room temperature in the case of IgM. Each antibody-coated ORBC preparation was then washed twice with PBS and subsequently resuspended to a final concentration of 1% in HBSS. T_G and T_M rosettes were prepared by the addition of 100 µl of antibody-coated ORBC to each of the 1×10^6 T-cell preparations followed by centrifugation at 200×*g* for 5 minutes and incubation at 4°C for 30 minutes. Rosetting cells were isolated on cold LSM as described above for T-cells. LAI reactivity was assessed in cells enriched for T_G cells or T_M cells. The recovery of cells under these circumstances was about 25% of the initial T-cell-enriched population. For such cell fractionation, 250 ml of whole blood was required from individual donors. Eight volunteers who were reactive to PPD by delayed hypersensitivity skin testing were tested for LAI reactivity, and all were positive. Four donors who were skin test-negative and nonreactive to PPD in the LAI assay were used as negative controls.

RESULTS

When tested with PPD across a wide range of concentrations, PBMC from skin test-positive donors gave consistently positive results by the LAI assay. No pattern of variation in the LAI reactivity across this range was apparent however, which is consistent with the observation that the LAI assay is a qualitative and not a quantitative assay (*7*). However, the upper and lower concentrations of 100 and 1 μg PPD/2×10^6 cells gave somewhat variable results. Consequently, a concentration of 10 μg/2×10^6 cells was used for subsequent experiments. On repeat testing over 1 year's time, no positive donor converted to negative.

Direct LAI With Various Cell Populations

Table 1 summarizes the effect on LAI responsiveness with the use of T-cell-enriched and T-cell-depleted cell populations in 6 donors with reactive PBMC. Whereas the T-cell-enriched cell subpopulation was consistently positive, the non-T-cell subset was always negative.

Further fractionation of T-cells into T_M and T_G cells demonstrated LAI reactivity by T_G cells only. The T_M-enriched subfraction was negative whether this subfraction was actively enriched for T_M cells by IgM–ORBC rosetting (table 2, expts 1 and 2) or whether it was the residual population remaining after T_G cell separation (table 2, expt 3).

LAI reactivity was tested in volunteers who were negative to PPD skin testing. Four donors were tested for LAI reactivity by their PMBC. Two were tested for T-cell reactivity and one for T_G and T_M cell reactivities (table 3). All tests were consistently negative, excluding the possibility that cell subfractionation techniques cause false-positive results.

An additional concern was that some cell separation techniques might impair the ability of the cell subfractions to respond to PPD in the LAI assay due to the nonspecific release of the active LAIF or due to impairment of its synthesis or secretion. Because isolation of either T_G or T_M cells requires six washes or more plus overnight incubation, separate experiments were performed to assess the effect on PBMC by either of these conditions. Table 4 demonstrates that neither extensive washing nor overnight incubation under conditions similar to those used for isolation of the T_G and T_M cell subpopulations affected normal adherence of PBMC to the glass hemacytometer slides, but both did prevent PBMC from specifically reacting to PPD. Thus although T_G and the total T-cell subpopulations are reactive following these procedures, PBMC failed to react. Overnight incubation of whole blood at 25°C with subsequent separation of PBMC resulted in normal reactivity, so that incubation in artificial media was required for loss of LAI response.

[a] Results are mean percentage adherent cells of four assays ± the standard error.

To assess further the reason for loss of LAI reactivity of PBMC following overnight incubation in artificial media, we collected the supernatant of the incubated cells and assessed it for LAIF. Table 5 demonstrates that LAIF activity was present in the spent media, suggesting that overnight incubation led to nonspecific release of this factor into the media. Although the PBMC failed to react under these conditions, T-cells and T_G cells separated from these populations continued to maintain their specific LAI reactivity.

Indirect LAI of Various Cell Subpopulations

Results with the use of the indirect LAI assay confirmed the release of LAIF upon specific antigen challenge by PBMC, T-cells, and T_G cells but not by non-T-cells or T_M cells (table 6). Because of the presence of PPD in the supernatant used for the LAIF assay, it was important to use a PPD-negative donor for tests for LAIF. The negative

[c] ND=not determined.

donor was the donor in experiment 4 (table 3) whose cells were confirmed to be unresponsive to PPD by direct LAI assay, which was performed concomitantly with the indirect assay. For the control samples, the various cell subsets were incubated in the standard fashion with RPMI-1640 as medium controls; however, when sufficient cells were available, a second control with the use of supernatants from cell subsets incubated without PPD was also run.

The impact of cycloheximide treatment on LAI reactivity was assessed in various experiments. Incubation of 2×10^6 PBMC with up to 50 μg cycloheximide for 1 hour yielded 90% viability by trypan blue exclusion, whereas 100 μg cycloheximide resulted in a decrease to 60% viability. A 24-hour incubation with as little as 10 μg cycloheximide resulted in a decreased viability to 20–30% of cells. T-cell sensitivity to cycloheximide demonstrated the same pattern as PBMC.

To test the adequacy of protein inhibition by cycloheximide, we incubated PBMC from a normal volunteer in leucine-free RPMI-1640 with FCS and phytohemagglutinin at a concentration of 1:500 as a nonspecific mitogen; we used the method of Rosenberg and Levy (*19*). A 1-hour or a 24-hour incubation with as little as 10 μg cycloheximide/ml completely suppressed protein synthesis as evidenced by tritiated leucine uptake. No further suppression by 25- or 50-μg amounts was noted.

Table 7 displays the results of cycloheximide incubation on LAI reactivity. Cycloheximide at 25 μg does not affect the glass adherence of T-cells and has no impact on LAI response to concomitant exposure to PPD. Adding 50 μg cycloheximide to T-cells for 1 hour significantly reduced the glass adherence. Despite this reduction, the concomitant addition of PPD caused further specific LAI reactivity. In addition, incubation of T-cells with 10–50 μg of cycloheximide for 24 hours before PPD stimulation did not prevent glass adherence or the specific LAI reactivity to PPD.

DISCUSSION

Moretta et al., (*16, 17*) and Ferrarini et al. (*18*) have defined subsets of human T-cells on the basis of cell surface receptors for either the Fc portion of IgG (T_G cells) or the Fc portion of IgM (T_M cells). The method used involved enumeration by rosetting T-cells with ORBC coated with subagglutinating doses of either anti-bovine erythocyte IgM or IgG. T-cells rosetting with anti-ORBC were termed "T_G cells," and T-cells rosetting with anti-ORBC IgM were termed "T_M cells."

In a related set of experiments with pokeweed mitogen-stimulated B-cell production of intracytoplasmic antibody, it was established that T_M cells were helper cells and that the T_G cells were suppressor cells (*20*). It was found that up to 20% of human peripheral blood T-cells were T_G cells or suppressor cells, and the bulk of the remainder consisted of T_M cells or helper cells (*21*). The cells could be isolated and separated by differential centrifugation after rosetting with IgM- or IgG-coated ORBC. The two subsets were found to differ in their response to phytohemagglutinin. Subsequent work showed that T_M and T_G cells could also be distinguished on the basis of morphologic and histochemical characteristics (*22*).

That T_G and T_M cells truly represent suppressor and helper T-cells in the peripheral blood of humans has not been definitely established. Indeed, it appears that not all T-cells with a cell surface receptor for the Fc portion of IgG are suppressor cells. Antibody-dependent cellular cytotoxicity and natural killer cell activity have also been described with this subpopulation (*23, 24*). T_M cells may elicit suppression upon interaction with concanavalin A (*25*). Conversion of T_G cells to T_M cells on incubation or upon interaction with immune complexes has been reported (*26*). With these provisos, T_G and T_M determinations do permit separation of subpopulations of T-cells that appear to have distinct functions.

The results of our experiments support these cell separation techniques as yielding functionally distinct cell subsets and indicate that T_G cells, mononuclear cells with receptors for both SRBC and the Fc portion of immunoglobulin G, possess the unique property of specific LAI activity. Others have observed that a small percentage of monocytes may be

necessary for LAI activity (27). Although small differences in the proportion of accessory cells in the various T-cell subpopulations may exist, the methods utilized for isolation of T-cells in these experiments yield less than 1% monocytes as assessed by latex ingestion and alpha napthylacetate esterase staining. Latex screening of T_G and T_M cells also demonstrates less than 0.1% contamination of these subfractions by monocytes. The fact that neither the non-T-cell nor the T_M cell subpopulations demonstrated LAI activity, with these subpopulations containing the same granulocyte and monocyte contaminants, makes it unlikely that these accessory cells are major participants in this LAI reactivity.

These experiments are consistent with the requirement of a secreted factor (LAIF) for inhibition of leukocyte glass adherence. We have shown that such a factor may be released into the media by overnight incubation in RPMI-1640 with 20% FCS and that exhaustive washing in HBSS or overnight incubation of cells in artificial media will cause a loss of the ability of PBMC to respond to antigen in the LAI assay, although normal glass adherence is not affected. Such a phenomenon seems most consistent with spontaneous release of LAIF by mechanical factors. It is also possible that the FCS may be responsible for the release of LAIF with overnight incubation in consideration of the observation that overnight incubation of unseparated whole blood did not impair LAI activity of PBMC. In any event, LAIF is demonstrable in the spent media after overnight incubation of PBMC; and, while the PBMC remain normally glass-adherent, they are unable to respond to specific antigen. We are unable to explain the observation that PBMC lose their ability to respond under these conditions, whereas T-cells, which constitute the majority of PBMC, will continue to respond under the same conditions when these cells are tested separately.

Specific release of LAIF by antigen challenge of sensitized cell subpopulations was demonstrated by the indirect LAI assay for T-cells as demonstrated by others (5, 6, 8). We have further characterized the cell subpopulation with this in vitro capacity to be erythrocyte rosette-positive and IgG Fc receptor-positive (T_G) cells. Several explanations for this difference between T_G and T_M cells are possible: T_G cells may bind LAIF more tightly, causing it to be resistant to release by the mechanical stresses and overnight incubation required in the isolation procedures, whereas non-T_G cells selectively lose this factor or the capacity to synthesize it. Thus this cell subpopulation may be the only one to have sufficient LAIF available for specific response to antigen in vitro. We have demonstrated that overnight incubation itself is not responsible for the lack of non-T-cells. Separation of T-cells from non-T-cells can be performed in 1 hour with the use of *Vibrio cholera* neuraminidase-treated SRBC. Separation and testing of T-cell and non-T-cell subfractions in 1 day with the use of this technique have not altered the LAI activity of the respective subfractions. An alternative possibility is that blocking factors may be released by some cell subsets, which then prevent specific LAI reactivity. These cell subsets with blocking activity may be selectively confined to non-T-cell and/or T_M cell subfractions. Active synthesis of LAIF may be a requirement, and only T_G cells may have this capacity. However, the continued LAI activity following 24-hour incubation with cycloheximide (an inhibitor of protein synthesis) argues against de novo protein synthesis as a requirement for specific LAI response by T-cells. Alternatively, a population of T_G cells may be truly distinctive in its ability to secrete LAIF in response to PPD as a specific antigen and thus be the major cell subset producing this lymphokine. Use of available monoclonal antibodies to define and isolate immunologically cell subsets may help to establish which of these several possibilities might explain the specificity of T_G cell LAI reactivity.

Interferon Effect on Cytotoxicity of Peripheral Blood and Tumor-Associated Lymphocytes Against Human Ovarian Carcinoma Cells[1,2,3]

Paola Allavena,[4] **Martino Introna,**[4] **Cristiana Sessa,**[5] **Costantino Mangioni,**[5] *and* **Alberto Mantovani**[4,6,7]

ABSTRACT—A study was done to investigate the tumoricidal activity of peripheral blood lymphocytes (PBL) and tumor-associated lymphoid cells (TAL) against freshly isolated tumor cells in human ovarian carcinoma. TAL and carcinoma cells were purified by density and velocity sedimentation on discontinuous Ficoll-Hypaque gradients and fetal bovine serum. Purified carcinoma cells from 23 ascitic and 3 solid tumors were used as targets in a 4- or a 20-hour ^{51}Cr release assay. K562 cells were used to measure natural killer (NK) activity. Freshly purified ovarian carcinoma cells were relatively resistant to lysis by normal unstimulated PBL. Cytolytic activity of ovarian cancer PBL and TAL did not exceed that of control PBL: Only one PBL preparation had high levels of cytotoxicity (36.2 and 42.9% specific lysis after 4 and 20 hr at an effector-to-target cell ratio of 50:1) against autologous cancer cells but not against allogeneic targets (<5% specific lysis). TAL and, to a lesser extent, ovarian cancer PBL showed impaired NK activity against K562 compared to the activity seen in controls. In vitro exposure to partially purified human fibroblast interferon (IFN) (1,000 U/ml for 1–18 hr) augmented NK activity against K562 of PBL and TAL. When ovarian carcinoma cells were used as targets, IFN enhanced the cytotoxicity of normal PBL in a 4- and 20-hour assay; stimulation by IFN was less frequently observed with ovarian cancer PBL and TAL in a 4-hour assay, but after 20 hours effector cells from tumor-bearing subjects showed IFN-boosted cytotoxicity against carcinoma cells similar to the degree of cytotoxicity seen in controls. IFN enhanced the cytotoxicity of PBL and TAL against both autologous and allogeneic carcinoma cells. Thus PBL and TAL are rarely cytotoxic against ^{51}Cr-labeled fresh autologous carcinoma cells, but in vitro exposure to IFN induced low levels of killing of ovarian tumor cells.—JNCI 1981; 68:555–562.

The in vitro cytotoxicity of lymphocytes has been considered one of the expressions of cell-mediated mechanisms of immune defense. For the evaluation of cell-mediated cytotoxicity against tumor cells in cancer patients, in vitro cultured cell lines have been extensively employed (*1*). Several methodologic factors, such as the susceptibility of cultured cells to NK cells (*2*), render the interpretation of the data on cytotoxicity against lines difficult.

Following a different experimental approach, in a series of studies freshly isolated, purified tumor cells, relatively resistant to NK lysis, were used in short-term ^{51}Cr release assays (*3–9*).

PBL from approximately 30% of cancer patients were cytotoxic against autologous tumor cells (*3–6*). In a recent study, in vitro exposure to IFN augmented lysis against allogeneic but not against autologous fresh cancer cells (*6*). Except for lung cancer, which has been studied extensively (*5, 6*), investigators using ^{51}Cr-labeled fresh solid tumor cells have studied heterogeneous series of neoplasms, mainly of mesenchymal origin (*3–6*). In the present study the cytotoxic activity of PBL and TAL was characterized in a homogeneous group of ovarian cancer patients with the use of freshly purified, ^{51}Cr-labeled carcinoma cells as targets.

MATERIALS AND METHODS

Human subjects.—Twenty-four patients with histologically confirmed ascites ovarian epithelial tumors admitted to the Department of Oncology, Clinic Ostetrica e Ginecologica, Università di Milano, formed the case list for this study (table 1). All patients had cancers classified as stages III and IV. Independent pathologists checked for the presence of tumor cells in ascitic fluids.

The control population consisted of 29 age-matched patients admitted to the same clinic for nonmalignant, noninfectious gynecologic disorders (e.g., benign ovarian cysts and myomas) and of 90 normal healthy adult volunteers.

Heparinized venous blood (10–50 ml) was obtained by venipuncture, and carcinomatous ascites was collected by paracentesis or at laparotomy. Solid tumor specimens were obtained during surgery.

PBL.—Blood was diluted 1:4 with PBS (Eurobio, Paris, France), and 40 ml was then placed on 10 ml Ficoll-Hypaque (Eurobio) for centrifugation at 400×*g* for 20 minutes at room temperature. Mononuclear cells were collected at the interface and washed with PBS, and $10–30\times10^6$ cells were incubated in 10–20 ml of RPMI-1640 medium supplemented with 20% FBS (Gibco-Biocult, Glasglow, Scotland) for 45 minutes at 37°C in plastic petri dishes (#3003; Falcon Plastics, Oxnard, Calif.). Nonadherent cells were collected, centrifuged at 400×*g* for 5 minutes, and finally resuspended in RPMI-1640 medium with 10% FBS or pooled human AB serum and 50 μg gentamicin/ml. Nonadherent cell preparations were only partially depleted of monocytes inasmuch as 2–4% of these cells as compared to 10–30% of the original mononuclear cell suspensions (*9*) were mononuclear phagocytes as assessed by morphology, avid uptake of neutral red,

and staining for nonspecific esterase.

TAL and ovarian carcinoma cells.—Enriched preparations of ovarian tumor cells and TAL were obtained by stepwise application of density and velocity sedimentation on discontinuous Ficoll–Hypaque or FBS gradients (*3, 4, 9*). Carcinomatous ascites was centrifuged at 400×*g* for 5 minutes. Cells were resuspended in PBS, and 20 ml of the cell suspension (1–5×10^6 cells/ml) was stratified on 10 ml Ficoll–Hypaque. The tubes (#25330; Corning Glass Works, Corning, N.Y.) were then centrifuged at 400×*g* for 20 minutes at room temperature and the mononuclear cell layer was aspirated. For removal of macrophages from ovarian ascites cell suspensions, mononuclear cells in serum-free medium (*9*) were incubated for 45 minutes at 37°C in plastic petri dishes. The procedure was repeated two to three times until contamination with mononuclear phagocytes, assessed by morphology and avid uptake of neutral red, was less than 5%. After being washed with 50 ml PBS, 10 ml of the mononuclear cell suspension (2×10^6/ml) was layered on discontinuous gradients consisting of 10 ml of 100% and 15 ml of 75% Ficoll–Hypaque. The tubes were centrifuged at 1,700 rpm for 10 minutes at room temperature. Lymphocyte-enriched suspensions were harvested at the 75–100% interface and tumor cells were found on top of the 75% fraction. The procedure was repeated once or twice if separation was not satisfactory. When separation of lymphocytes from tumor cells on discontinuous Ficoll–Hypaque gradients was not satisfactory, as judged by morphologic examination of Wright-stained smears, cell suspensions (10–20×10^6/10 ml PBS) were layered onto 10 ml fetal calf serum and incubated at room temperature for 60–90 minutes; tumor cells sedimented at the bottom of the discontinuous gradient, whereas cells with lymphoid morphology remained in the upper part of the gradient. The various phases of the separation procedure were monitored by morphologic examination of Wright-stained smears. Unseparated tumor cell suspensions and the purified lymphocytes or tumor cells were prepared with Papanicolaou's stain and occasionally examined by independent pathologists. Lymphoid cell and tumor cell suspensions were accepted for use when at least 95% (usually >98%) of the cells had the typical unequivocal morphology of the respective cell type. On the average, 50% of TAL had receptors for sheep erythrocytes and 18% for complement-coated zymosan (*9*). Less than 5% of the lymphoid cell suspensions belonged to the monocyte–macrophage lineage, as assessed by morphology, rapid uptake of neutral red, and nonspecific esterase staining, and work in progress shows that TAL have a significant blastogenic response to phytohemagglutinin. Primary ovarian carcinoma cultures with typical morphology and lack of contact inhibition could be established from purified tumor cells (*9*), but attempts to cultivate tumor cells from lymphocyte preparations consistently failed. Viability of enriched fractions always exceeded 90% and lymphocyte recovery ranged from 50 to 0.5×10^6 cells for different patients. When normal PBL were submitted to the same separation procedure used for ovarian tumors, NK activity was not significantly affected.

In addition to ovarian tumors, in 1 experiment TAL from a malignant effusion from a uterine carcinoma was employed (identified in the tables and text-figs.).

For the isolation of ovarian cells and tumor-associated lymphocytes from solid tumors, specimens were minced mechanically and then exposed for 45 minutes at 37°C to 0.3% collagenase (#40130; Sigma Chemical Co., St. Louis, Mo., or Worthington Biochemical Corp., Freehold, N.J.) in BME (Eurobio) containing 10 μg DNase/ml. After two washes with 50 ml BME, disaggregated cells were then treated as described above for the cellular preparations isolated from the ascitic fluids.

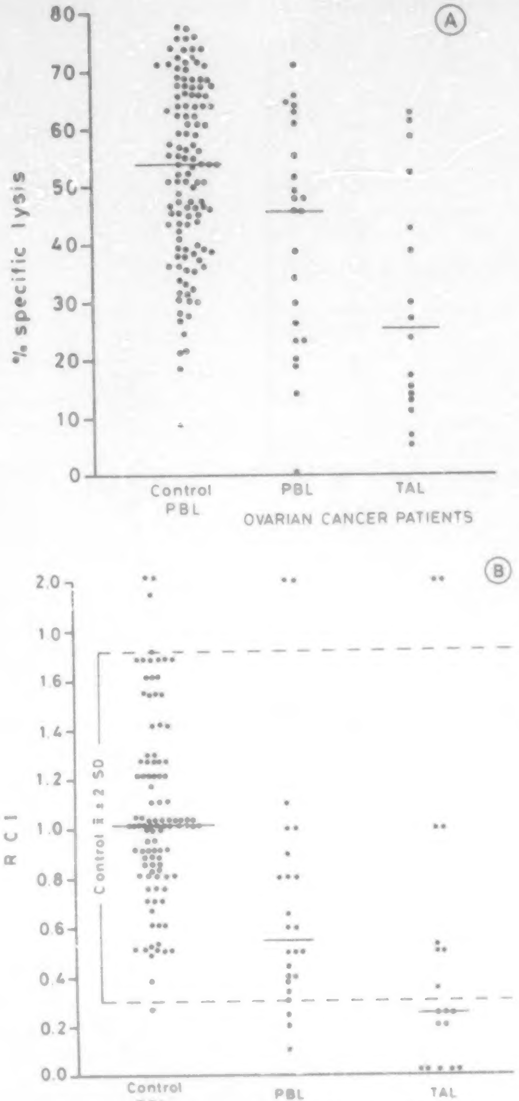
IFN.—Partially purified human fibroblast IFN (lot #45-10-9) was obtained from HEM Research Inc., Rockville, Md. Lymphoid cells ($1-5\times10^6$/ml) were cultured for 18 hours in the presence of 1,000 U IFN/ml in growth medium. Control lymphocytes were cultured alone. Lymphoid cells were washed with 50 ml PBS before their cytotoxic capacity was tested. In two experiments (*see* "Results") lymphocytes were exposed to IFN for shorter periods (1-6 hr) under the same conditions.

Target cells.—NK activity of PBL and TAL was measured with the use of K562 cells (*10*) as targets. K562 cells and freshly purified ovarian carcinoma cells ($1-5\times10^6$ cells in 1 ml growth medium) were incubated with 20-50 μCi of ^{51}Cr (Radiochemical Centre, Amersham, Buckinghamshire, England) at 37°C for 45 minutes. Labeled cells were washed twice with 50 ml of BME before use in cytolysis assays.

Cytotoxicity assay.—^{51}Cr-labeled tumor cells (10^4) were cultured in 0.2 ml RPMI-1640 medium with 10% serum in round-bottomed wells of MicroTest plates (Sterilin Ltd., Teddington, Middlesex, England). FBS was used in part of the experiments; after it became difficult to obtain, FBS was replaced with pooled human AB serum. Cytotoxicity data were similar in the two series of experiments. The routinely employed A:T was 25:1 or 50:1 for ovarian carcinoma cells. Lysis of K562 was routinely measured at A:T ranging from 6:1 to 50:1, but only data at A:T of 25:1 will be presented. Isotope release was determined after 4 and 20 hours of incubation, except for occasional experiments in which cytotoxicity was measured only at 20 hours. Isotope release was calculated as $(A/B)\times100$, where A is the isotope in the supernatant and B is the total incorporated radioactivity released by incubation with 1% sodium dodecyl sulfate in water. Specific lysis was calculated by subtraction of the spontaneous isotope release of tumor cells alone. Spontaneous ^{51}Cr release from ovarian carcinoma cells ranged from 6 to 43% after 4 hours of incubation and from 25 to 49% after 20 hours (table 1). In eight experiments, control cultures to which unlabeled ovarian carcinoma cells were added instead of lymphocytes were included; isotope release was not different from that of labeled target cells alone.

Statistical analysis.—At least three replicates per experimental group were employed throughout, and results of cytotoxicity tests were calculated as mean plus or minus the standard deviation; 4-6% increases in isotope release above base line were usually statistically significant at $P<0.05$ (Duncan's new multiple-range test).

In each NK experiment against K562, ovarian cancer lymphocytes were tested along with at least 3 control subjects. A semilog plot of the specific cytotoxicity data against the number of effector cells per sample was obtained; the number of effector cells required for 33% specific lysis was arbitrarily referred to as LU33. For each lymphoid cell preparation an RCI was calculated as: $\bar{X}n$ LU33/t LU33, where $\bar{X}n$ LU33 is the average LU33 value for control subjects tested concomitantly and t LU33 is the same for the test subject. Thus an RCI of 0.2 indicates that five times more test lymphocytes are required to obtain 33% lysis when compared to the amount of lymphocytes required by control effector cells. NK data were expressed also as RCI, because this procedure reduced the day-to-day coefficient of variation of the assay (*9*, *11*, *12*).

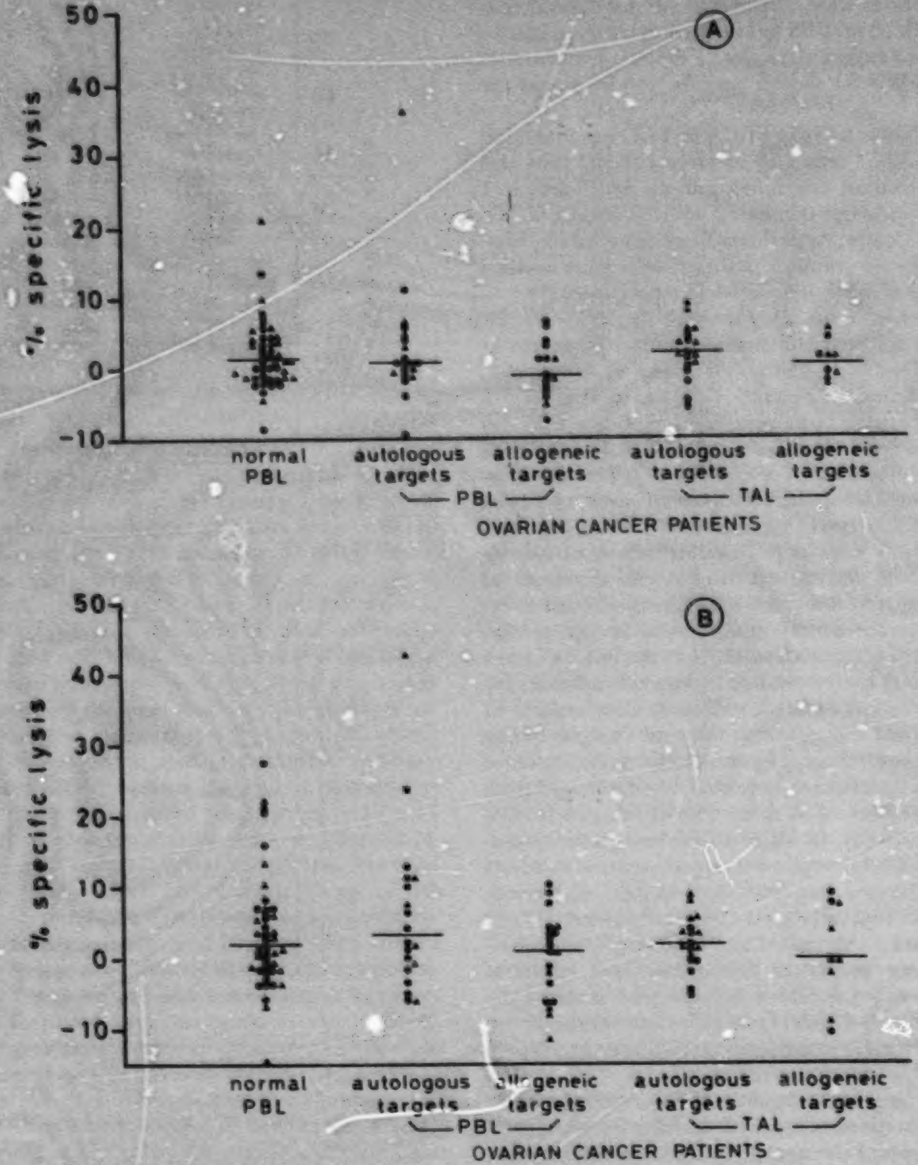


TEXT-FIGURE 1.—NK activity against K562 cells of PBL and TAL from ovarian cancer patients. Results are presented as percentage of specific lysis at an A:T of 25:1 (A) or as RCI (B). Cytotoxicity values from normal PBL were significantly higher than those for PBL ($P<0.01$) and TAL ($P<0.01$) from ovarian cancer patients.

RESULTS

In agreement with previous data (*9*), PBL and TAL from patients with ovarian tumors had impaired NK activity against K562 compared to the NK activity in control subjects. Cytotoxicity of TAL was lower than that of PBL from the same patients (text-fig. 1A, B).

Freshly isolated ovarian carcinoma cells were relatively resistant to lysis by unstimulated normal PBL (*9*). In only 5 of 35 experiments, significant lysis (>5% above background) was observed after 4 hours of culture. After 20 hours of interaction in 10 of 25 experiments, cytotoxicity was observed, the cytolysis values ranging from 5 to 27%. When PBL or TAL from ovarian cancer patients were tested against autologous or allogeneic tumor cells, on the whole the cytotoxicity of effector cells from tumor-bearing subjects was not greater or more frequently observed than that of control subjects (text-fig. 2A, B). Only PBL from 1 donor (of target cell #24) showed high levels of killing against autologous tumor cells, which clearly exceeded levels of killing of normal PBL: At an A:T of 50:1, specific lysis was 36.2% at 4 hours and 42.9% at 20 hours. The same PBL from the donor of target cell #24 were not cytotoxic against an allogeneic tumor (#4; specific lysis, 3.9% at 20 hr) nor were allogeneic ovarian cancer effectors lytic on #24 target cells. We could test PBL and cancer cells from the donor of



TEXT-FIGURE 2.—Cytotoxicity of PBL and TAL from ovarian cancer patients against autologous and allogeneic ovarian tumor cells. Cytolysis was measured in a 4-hr (A) and a 20-hr (B) assay with the use of an A:T of 25:1 (●) or 50:1 (▲). *Horizontal bars* indicate the medians.

target cell #24 only once.

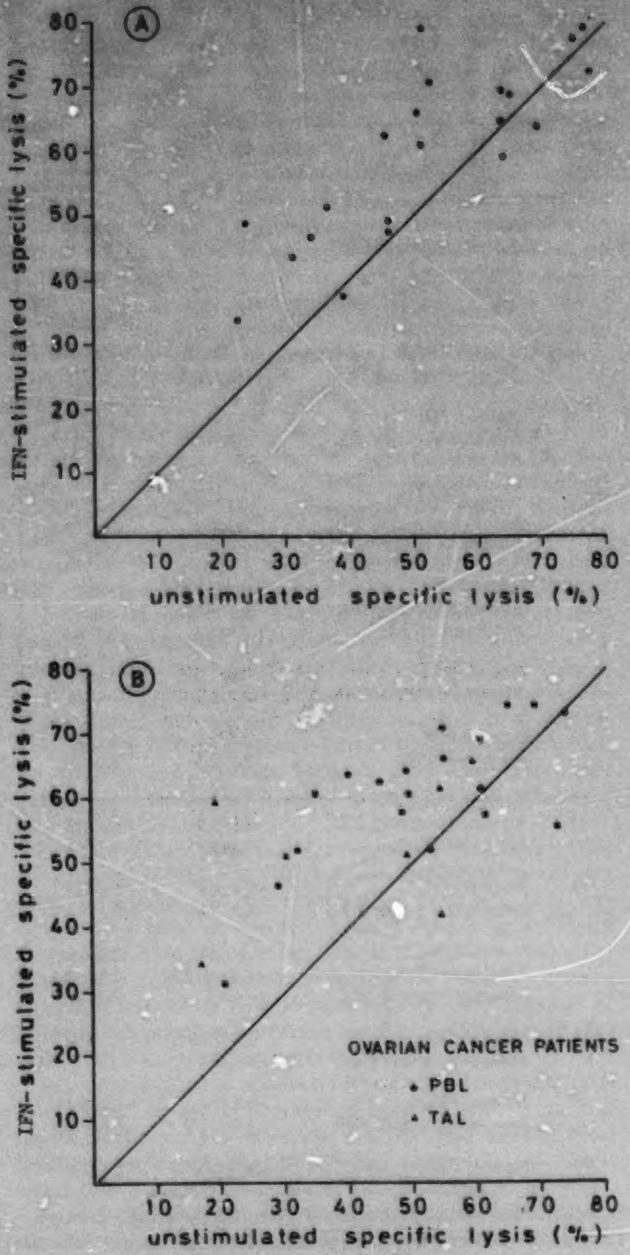
In vitro exposure to IFN augments NK activity [reviewed in (*2*)]. It was therefore of interest to evaluate whether IFN-boosted effectors killed ovarian carcinoma cells, relatively resistant to base-line cytotoxicity of unstimulated effectors. Lysis of K562 cells was measured as a positive control for stimulation of NK activity by IFN. As shown in text-figure 3A, IFN (1,000 U/ml) enhance the NK activity against K562 of PBL from normal donors and of TAL and PBL from ovarian cancer patients (text-fig. 3B). Treatment with IFN did not always augment the cytotoxicity against K562. In fact, in 6 of 22 normal PBL and 7 of 26 ovarian cancer PBL and TAL, no increase in NK activity was observed. Inasmuch as only one exposure time (20 hr) and IFN concentration (1,000 U/ml) were used routinely, we cannot exclude that refractoriness of these preparations to IFN was related to these particular experimental conditions.

Results of cytotoxicity of ovarian carcinoma cells by IFN-stimulated effector cells are detailed in table 2, and the overall results are summarized in table 3. Against most carcinoma cells studied, IFN-treated normal PBL had significant cytolytic activity or, if unstimulated effectors already expressed some measurable cytolysis, this expression was enhanced after exposure to IFN. Stimulation of normal PBL cytotoxicity was already detectable after 4 hours of incubation (12/20 positive tests as compared to 12/19 at 20 hr) and absolute increases in lysis ranged from 5 to 40% with different targets (tables 2, 3). When PBL from ovarian cancer patients were used as effectors (table 2), stimulation of cytotoxic activity against autologous or allogeneic tumor cells was observed rarely at 4 hours; significant boosting was detected with 3 of 13 (autologous effectors) and 2 of 10 (allogeneic effectors) tumor cell preparations ($P<0.05$ vs. control PBL value; table 3). However, after a 20-hour assay, the cytolysis was significantly augmented in 8 of 14 carcinomas tested with autologous effectors and 4 of 11 tested with allogeneic PBL. In 3 (#8, 13, 18; table 2) of the 8 tests in which IFN-treated PBL caused more lysis than unstimulated effectors, cytotoxicity did not exceed isotope release of tumor cells alone, because untreated PBL had a significant "feeding" effect on targets abolished by IFN. When one considers the effects of IFN on cytotoxicity against autologous carcinoma cells, it is noteworthy that IFN decreased the tumoricidal activity of PBL from the donor of target cell #24 (from 42.9 to 31.1; 20 hr; table 2) whose effectors expressed appreciable levels of cytolysis against the autologous targets.

A limited number of TAL were tested for cytotoxicity against autologous or allogeneic tumor cells after exposure to IFN (table 2). Results were similar to those with PBL, and 5 of 9 and 3 of 5 tumor cell preparations tested with autologous and allogeneic effectors showed a significant augmentation of the cytotoxicity expressed by TAL after a 20-hour test.

DISCUSSION

Freshly isolated human ovarian carcinoma cells were relatively resistant to lysis by normal unstimulated PBL (*9*). Resistance to NK of tumor cells not cultured in vitro has also been observed with other human solid neoplasms and



TEXT-FIGURE 3.—Effect of IFN on NK cytotoxicity against K562 cells of normal PBL (A) and ovarian cancer PBL and TAL (B).

leukemias (*3–9*). However, in agreement with previous data (*9*) low, but significant, natural cytotoxicity against ovarian carcinoma cells was occasionally observed and was best observed after a 20-hour assay.

In previous studies with different human tumors, in approximately 30% of the patients, evidence for cytotoxicity of PBL preferentially expressed against autologous tumor cells was obtained (*3–6*). In the present study only 1 subject had cytolytic activity against autologous tumor cells that clearly

[a] Effector cells were tested at an A:T of 50:1 or 25:1. Effector cells were exposed to IFN for 20 hr except for experiments with target #19 and 26 in which lymphocytes were incubated with IFN for 6 and 1 hr, respectively.

[b] Duration of the ^{51}Cr release assay. Release below that of tumor cells alone, −. NT=not tested.

[c] Lysis of lymphoid cells exposed to IFN significantly above that of unstimulated effectors ($P<0.05$).

[d] Carcinoma cells from solid primary tumor.

[e] Allogeneic cancer PBL and TAL were from a uterine tumor.

exceeded that of normal control PBL. Interestingly enough, PBL of this patient did not kill allogeneic carcinoma cells as usually observed in other human tumors with the use of a similar experimental approach (*3–6*). Several factors, in addition to a different immunobiology of the tumors studied, can account for the low frequency of reactivity of PBL against autologous ovarian carcinoma cells observed in the present investigation at variance with previous reports of other tumors. For instance the ovarian tumors considered in the present study were stage III or IV, because ovarian carcinoma is usually diagnosed very late, and autologous reactivity in other neoplasms was more frequently detected at early disease stages (*3, 4*). Moreover, weak reactivities may have been masked by the significant cytotoxicity observed occasionally with normal donor PBL.

Lymphoid cells isolated from ascites ovarian tumors did not show cytotoxicity against autologous or allogeneic ovarian carcinoma cells. Similarly, TAL from various human solid neoplasms did not kill tumor cells in a ^{51}Cr release assay, even when PBL from the same patient were reactive (*4–5*). However, intratumor cytotoxic lymphocytes were found in nasopharyngeal carcinoma and in Burkitt's lymphoma (*4, 13*), and, using a visual microcytotoxicity assay, Werkmeister and co-workers (*14*) reported intratumor cytotoxicity in colorectal cancer even when PBL were not active. Although in the case of colorectal cancer the use of a visual microcytotoxicity assay (*14*) renders comparisons with these and previous data difficult, it is conceivable that

TABLE 3.—*Augmentation by IFN of cell-mediated lysis of fresh ovarian carcinoma cells*

Effector cells	Incubation time, hr	Tumor cells with stimulation of lysis/total	Absolute increase in lysis[a]
Normal PBL	4	12/20	7.6 (5–17)
	20	12/19	8.9 (5–42)
Patient PBL (autologous)	4	3/13[b]	10.3 (5–15)
	20	8/14[c]	6.7 (5–11)
Patient PBL (allogeneic)	4	2/10[b]	9.3 (6–12)
	20	4/11	11.3 (7–23)

	20	5/9[d]	6.8 (5–13)
Patient TAL (allogeneic)	4	3/5	5.3 (5–7)
	20	3/5	9.6 (5–16)

[a] Results are mean absolute increases in lysis (with ranges *in parentheses*) of IFN-stimulated effectors above unstimulated lymphocytes. Only experiments (see table 2) in which IFN caused a significant ($P<0.05$) augmentation of lysis were used to calculate the mean.

[b] $P<0.05$ compared to value of normal PBL tested at 4 hr; Fisher's exact test.

[c] With 3 tumor cell preparations (#8, 13, 18), isotope release of tumor cells with unstimulated effectors was significantly lower than that of tumor cells alone (table 2).

[d] Same as *footnote c* for two preparations (#1 and 8, table 2).

differences in the reactivity of intratumor lymphocytes are related to a different immunobiology of the neoplasms investigated.

Preliminary evidence for the presence of intratumor suppressor cells for lymphoproliferative responses (*15*) and for NK activity (*9, 16*) has been obtained in selected human neoplasms. The possible role of suppressor cells in the lack of cytotoxicity of TAL observed in this study and in other studies (*3–5*) remains to be elucidated.

Ovarian carcinoma cells were relatively resistant to lysis by normal unstimulated PBL (*9*). In agreement with previous preliminary data (*9*), in vitro exposure to IFN enhanced the cytotoxicity of normal PBL against freshly isolated ovarian tumor cells and this enhancement was observed in both a 4-hour and a 20-hour cytolysis assay. IFN also enhanced NK cytotoxicity against K562 of PBL and TAL from ovarian cancer patients, but stimulation of lysis of ovarian carcinoma cells in a 4-hour assay was observed less frequently with cancer effectors than with normal PBL. After 20 hours of interaction with targets, stimulation of lysis of fresh tumor cells was similar in frequency and magnitude to that observed with control PBL. It is tempting to speculate that the failure to find a consistent enhancement of lysis by IFN-treated tumor PBL and TAL after 4 hours of interaction with carcinoma cells is related to the impaired base-line NK activity of these effectors, which, according to this hypothesis, would require a longer interaction with the resistant target cells to reach the threshold of lysis.

Vánky et al. (*6*) have recently reported that IFN augmented the cytotoxicity of PBL from tumor-bearing patients against fresh cancer cells, provided the targets were from a different subject. On this basis they speculated that alloantigens are important in natural cytotoxicity under these conditions. Results reported here with a homogeneous series of ovarian cancer patients are clearly different from those of Vánky et al. (*6*). IFN-stimulated PBL or TAL from ovarian cancer patients were frequently cytotoxic against autologous tumor cells in a 20-hour assay. Both at 4 and 20 hours, no difference was observed in the cytotoxicity of ovarian cancer effector cells against autologous or allogeneic tumor cells, lymphoid cells from tumor-bearing patients being less reactive than normal PBL. Several factors, such as the different source of IFN, different preincubation time, and varying lengths of the assays, might partially account for the apparent discrepancy between results reported here with ovarian cancer and previous observations by Vánky et al. (*6*). For instance in our study, PBL or TAL were routinely exposed overnight to IFN before cytotoxicity was tested, whereas Vánky et al. (*6*) used a shorter preincubation. However, stimulation of cytolysis of autologous ovarian tumor cells was observed also in two experiments in which effectors were exposed to IFN for 1 or 6 hours (table 2) (target #26 and 19, respectively). Therefore, the apparent discrepancy between data reported here and previous data by Vánky et al. (*6*) possibly is related to differences in the immunobiology of the tumors investigated. In this context, it is of interest that mature NK cells were reported to kill allogeneic but not autologous fibroblasts; however, after stimulation, killing was detected against both autologous and allogeneic targets (*17*).

In some of the ovarian cancer patients, IFN enhanced the cytotoxicity of PBL and TAL against autologous carcinoma cells. In addition to stimulating NK lysis (*2*), IFN was reported to enhance specific T-cell-mediated cytotoxicity (*18*), and one might speculate that IFN-boosted cytolysis of autologous carcinoma cells is mediated by mature T-cells. Characterization of IFN-boosted effector cells capable of lysing autologous fresh ovarian carcinoma cells should elucidate the nature of this reactivity.

In conclusion, our results indicate that lymphoid cells from blood or ascites tumors of patients with advanced ovarian cancer, with impaired NK activity, usually have little cytotoxicity against freshly isolated autologous carcinoma cells, not exceeding that of PBL from control subjects; only in 1 of 24 patients did we observe appreciable killing of autologous, but not allogeneic, targets by PBL. Therefore, it is unlikely that lymphocyte-mediated cytotoxicity can act as a significant mechanism of restraint of the growth of these advanced neoplasms. In a few patients, in vitro exposure to IFN augmented the cytotoxicity of PBL and TAL against autologous or allogeneic fresh tumor cells. However, IFN-boosted cytolysis was usually low. Whether these levels of killing can have in vivo significance remains to be elucidated.

Morphologic Transformation and Chromosomal Changes Induced by Chemical Carcinogens in Skin Fibroblasts From Patients With Familial Adenomatosis Coli[1,2]

Michiko Miyaki,[3] Noriko Akamatsu,[3] Tetsuo Ono,[3] Akira Tonomura,[4] *and* Joji Utsunomiya[5,6]

ABSTRACT—Skin fibroblasts from patients with familial adenomatosis coli (AC) and normal individuals were treated once with the carcinogen 4-nitroquinoline 1-oxide or *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine and then passaged sequentially. Morphologically altered cells appeared in the cultures of carcinogen-treated AC fibroblasts at passages 6–8 (days 100–140) after treatment with the carcinogens, but carcinogen-treated normal cells and untreated AC and normal cells did not become altered even after cultivation for 25 passages. The cultures containing morphologically altered cells showed characteristics of transformed cells, such as a high frequency of colony formation in soft agarose, increased growth ability, and chromosomal abnormalities. The results suggest that AC patients have increased susceptibility to morphologic transformation and chromosomal changes induced by chemical carcinogens.—JNCI 1982; 68:563–571.

Individuals with familial AC, characterized by adenomatous polyps in the colon and rectum (*1*), have a high incidence of colon cancer and various other tumors, such as osteosarcoma (*2*), liposarcoma, and stomach cancer (*3*). Cultured skin fibroblasts from patients with this autosomal dominant trait have been reported to exhibit several growth abnormalities. The higher saturation density (*4*, *5*), higher plating efficiency (*5*, *6*), and lower serum requirement of AC fibroblasts (*4*) compared to those of cells from normal individuals suggested that AC fibroblasts partly resemble established cell lines. Different responses of AC and normal cells to a tumor promoter have also been reported by Kopelovich et al. (*7*) who demonstrated the acquisition of transplantability of AC fibroblasts into the anterior chamber of the eye of an athymic mouse after the fibroblasts were cultivated with TPA. The high susceptibility of AC fibroblasts to transformation by Kirsten MuSV (*8*) and pseudotypes of Moloney MuSV (*9*) indicates that these cells have a genetic factor similar to that in cells from other inherited high-risk groups of cancers, which have been reported to be susceptible to tumor viruses. In addition to the effect of virus, significant influences of physical and chemical carcinogens on genetic predisposition to cancer have been described in cases of some recessively inherited disorders. We have previously observed that skin fibroblasts from some individuals with manifest AC were more susceptible to the cytotoxicities of 4-NQO and mitomycin C than were cells from normal individuals, whereas the sensitivities of AC cells to MNNG and UV light were normal in regard to colony-forming ability (*5*). The present investigation was undertaken to examine the transformation of AC cells by these chemical carcinogens. This paper reports the morphologic transformation and chromosomal changes induced in AC fibroblasts by 4-NQO and MNNG.

MATERIALS AND METHODS

Fibroblasts were obtained by biopsy of skin from the left elbows of patients with familial AC and from normal individuals. The fibroblast AC(MS) was obtained from an AC patient (female, 45 yr old), and the fibroblast AC(YK) was obtained from a member of an AC family (male, 14 yr old). The normal cells, normal(MY) and normal(OK), were cultured from skin biopsy specimens obtained from normal individuals, a 29-year-old female and a 38-year-old female, respectively. Primary cultures were made by explantation, and cells were used at passage 10 after isolation. The cells were cultivated at 37°C in 5% CO_2 in air in EMEM (Nissui Seiyaku Co.) supplemented with 13% heat-inactivated (56°C, 30 min) FBS (GIBCO), 100 μg pyruvate/ml, 100 U penicillin G/ml, and 60 μg kanamycin/ml, and the medium was changed twice a week. When the cultures became confluent, the cells were detached from the glass dish by incubation with 0.016% Pronase E (Kaken Chemicals) and 0.02% EDTA at 25°C for 15 minutes. The cell suspension was centrifuged at 800 rpm for 5 minutes to remove Pronase, and then the cells were replated.

Transformation experiments were done by treatment of AC and normal cells for 1 hour with 4 or 8 *μM* 4-NQO or 40 *μM* MNNG in EMEM 24 hours after inoculation at a density of 2×10^6 cells/100-mm glass dish (6 dishes; 1.2×10^7 cells total for each experiment); the cells were then washed and cultivated in medium containing 13% FBS. The cultures were passaged successively at one-sixth the original cell density or at 5×10^5 cells/dish. At each passage, all cells from six dishes were combined and replated on the next six dishes. When morphologic alteration of the cells was observed or

the cells had been passaged 10–14 times, the cultures were tested for colony formation in soft agarose and for their chromosome number.

Cytotoxicities of carcinogens were determined by measurement of the cell numbers 7 days after treatment of the cells with 4-NQO and MNNG.

We measured the saturation density 14 days after seeding 1×10^4 cells/cm^2. The medium containing 13% FBS was changed every 3 days.

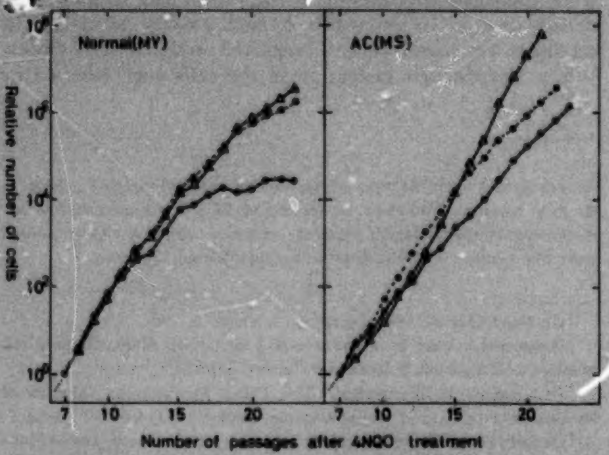
Growth of cells in agarose was determined as follows: The cells were detached from dishes with Pronase and EDTA, washed, and suspended at 2×10^3/ml in 0.2% agarose containing 20% FBS, 100 µg pyruvate/ml, and 0.1% polypeptone. The suspensions (2.5 ml each) were layered on 0.5% agarose (10 ml) in 60-mm dishes, and colonies were counted after cultivation for 4–8 weeks. We used 8–16 agarose plates for each experiment.

Mitotic cells were counted after treatment of cells with 0.1 µg Colcemid/ml for 2 hours and preparation of chromosome specimens by the air-drying method with the use of acetic acid–methanol for fixation and Giemsa for staining.

RESULTS

The AC fibroblasts from patients with familial AC used in this study were highly sensitive to transformation by MuSV (*9*) and showed a 10–20% higher saturation density compared to that of normal cells (*5*), but their growth rate was similar to that of normal cells in medium containing 13% FBS. The AC and normal cells were all diploid at the beginning of the transformation experiments.

AC and normal fibroblasts were treated for 1 hour with 4-NQO or MNNG and then sequentially passaged at intervals of 2–3 weeks. The cumulative growth curves of 4-NQO-treated and solvent-treated cells are shown in text-figure 1. The growth of solvent-treated normal(MY) cells stopped at passage 18, and the growth rate of 4-NQO-treated normal cells decreased gradually from passage 20 after treatment with the carcinogen. In contrast, solvent-treated AC cells still proliferated at passage 20, and the growth rate of 8 *µM* 4-NQO-treated AC(MS) cells began to increase at passage 10 after treatment. This increase in growth rate was accompanied by transformation of the cells. Morphologically altered cells began to appear among the AC fibroblasts (fig. 1B) at passages 6–8 (days 100–140) after treatment with 8 *µM* 4-NQO. These altered cells were small and spindle shaped with a disorganized arrangement, and the proportion of altered cells increased during subsequent passages. Cells from all of the subculture dishes derived from 8 *µM* 4-NQO-treated AC(MS) cultures were morphologically changed. The morphologic alterations in the 4 *µM* 4-NQO-treated AC(MS) culture were less than those in the 8 *µM* 4-NQO-treated cells, and the cumulative growth rate did not change significantly.



TEXT-FIGURE 1.—Cumulative growth curves of 4-NQO-treated normal and AC fibroblasts. The fibroblasts were treated with solvent or 4-NQO and then passaged at intervals of 2–3 wk. The number of cells per dish was measured at each passage, and the relative number of cells was plotted. ○——○, solvent. ●— —●, 4 *µM* 4-NQO. △——△, 8 *µM* 4-NQO-treated cells.

MNNG at 40 *µM* also induced morphologic changes in AC(MS) cells. However, neither carcinogen-treated normal cells nor solvent-treated cells (fig. 1A) became morphologically altered, even when cultivated for 25 passages in glass dishes.

The marked increase in colony-forming frequency (table 1) coincided with the morphologic alteration of the cells; e.g., after 10 passages the 8-*µM* 4-NQO-treated and the 40-*µM* MNNG-treated AC(MS) cells showed high efficiencies of colony formation in agarose, although their efficiencies at passage 3 were as low as those of solvent-treated cells. Colonies of MNNG-treated AC(MS) cells were larger (0.7–0.15 mm in diameter) than those of 4-NQO-treated AC(MS) cells (0.05–0.1 mm) (fig. 2).

The saturation density of carcinogen-treated AC(MS) cells was higher than that of solvent-treated cells (table 1). The proportion of mitotic cells in AC(MS) cultures treated with 8 *µM* 4-NQO or 40 *µM* MNNG was higher than that of normal cells in culture (table 1), and some of the round cells became detached from the dish during cultivation. Deep infolding of the nuclear membrane was also frequently observed in carcinogen-treated AC(MS) cells (table 1).

Chromosomal abnormalities appeared at the same time as the acquisition of colony-forming ability in soft agarose. The chromosomal aberrations are indicated in table 2. At metaphase, 44 and 35% of the 8 *µM* 4-NQO-treated and 40 *µM* MNNG-treated AC(MS) cells were hypotetraploid. The aneuploid cells in the carcinogen-treated AC(MS) cultures contained dicentric chromosomes at a frequency of 10–17% of the total mitotic cells (table 2), and the examples are shown in figure 3A and 3B. Metaphase cells in solvent-treated control cultures of this AC(MS) cell line contained no dicentric chromosomes (fig. 3D). The existence of these unusual chromosomes suggests that interchromosomal exchange occurred frequently in AC cells during long passages after treatment with carcinogens. The chromosomal change to aneuploidy and the appearance of an unusually large marker chromosome were also observed in another cell line, AC(YK) (table 2), although morphologic change of these cells was slight. In 4-*µM* 4-NQO-treated AC(YK) cells, 67% of the mitotic cells were hypotetraploid and 44% of the total mitotic cells contained an unusually large marker chromosome (fig. 3C). These AC(YK) cells exhibited tetraploidy

[a] Normal and AC fibroblasts were treated with carcinogen and then passaged. At passages 10–14 (days 140–200) after treatment of cells with carcinogen, the growth properties were measured as described in "Materials and Methods." The experiments for normal(MY) and AC(MS) were done with the use of glass dishes, and those for normal(OK) and AC(YK) were done with the use of plastic dishes. The mitotic coefficient and percentage deep infolding of the nuclear membrane were calculated from observations on 600–1,900 cells in each sample.

[b] Mean value obtained from two dishes.

[c] Means ± SE from 8 to 16 agarose plates.

[a] Cultures of fibroblasts at passages 10–14 (days 140–200) after treatment with carcinogen or solvent were incubated with Colcemid. Chromosome specimens were prepared as described in "Materials and Methods." Chromosomal abnormalities were estimated from examination of 90–130 mitotic cells in each sample.

[b] Mean chromosome number obtained from 15 to 55 mitotic cells containing near-4n chromosomes in each sample (means ± SE).

[c] Dicentrics and an unusually large monocentric chromosome.

after treatment with solvent alone, but the chromosome number was nearly 92 and no marker chromosome was found in this control experiment (figs. 3E, 3F).

The normal cell lines [normal(MY) and normal(OK)] did not show any dicentric chromosomes, and almost all mitoses were diploid (table 2), except for those in the 8-*μM* 4-NQO-treated normal(MY) cell line. This cell line exhibited tetraploidy after treatment with 8 *μM* 4-NQO and subsequent culture, but the cells were not altered morphologically.

The experiments on AC(MS) and normal(MY) were attempted twice, and the transformation of AC(MS) cells and the unchanged morphology of normal(MY) cells were reproducible. The morphologically transformed AC(MS) cultures at passages 10–14 after treatment with 8 *μM* 4-NQO or 40 *μM* MNNG, however, did not form tumors in BALB/c nude mice when inoculated sc at 10^7 cells per mouse. These morphologically transformed cells continued to grow for 330 days (25 passages) after treatment with carcinogens. A colony in soft agarose obtained from the 120th day of culture of 40-*μM* MNNG-treated AC(MS) cells grew during a further 270 days in a liquid medium after a 60-day culture in agarose, but the growth rate gradually slowed down. The cells are still growing very slowly, and cloning of the transformed cells is in progress.

DISCUSSION

The increase in colony-forming efficiency in soft agarose has been widely used as a parameter of neoplastic transformation. The AC cells treated with 4-NQO and MNNG in the present experiment showed a high efficiency of growth in agarose, and the number of passages required for acquisition of the ability to grow in agar was consistent with that previously reported for transformation of human fibroblasts (*10*). The morphologically transformed cells also exhibited chromosomal aberrations, such as polyploidy, aneuploidy, and formation of dicentric chromosomes or abnormal marker chromosomes. However, the normal cell lines did not show morphological alteration during sequential passage after treatment with carcinogens. The structures of chromosomes in the normal cells were rather stable, since neither dicentric nor remarkably abnormal chromosomes were formed on carcinogen treatment and subsequent passages.

The chromosomal changes in human cells have been suggested to be correlated with the acquisition of other characteristics of cellular transformation (*11–13*). There are few reports on chemical transformation of human cells from normal tissues (*10, 11, 14*), and the low rate of transformation of human cells in culture has been considered to be due to the stability of chromosomes. It is significant that abnormal chromosomes were frequently observed in morphologically transformed AC cells in the present study. Some AC cells have been reported to exhibit frequent spontaneous reciprocal translocations between chromosomes (*15*), and epithelial cells from patients with Gardner's syndrome (*16*) showed increased tetraploidy during cultivation. Increased numbers of chromosomal breaks have been observed immediately after treatment of AC cells with MNNG (*17*). These observations and the present results suggest that AC is susceptible to chromosomal aberrations that might be correlated with the high risk of cancer for patients with AC and the high frequency of transformation of the fibroblasts by oncogenic viruses (*8, 9*), a tumor promoter (*7*), and chemical carcinogens (*18, 19*).

With respect to the mechanism of susceptibility of AC to chemical transformation, the difference in the extents of damage of AC and normal cells on 4-NQO treatment should be considered. Even when normal cells were treated with a concentration of 4-NQO higher than that causing damage of AC cells, they showed no morphologic alteration. In addition, untreated AC cells have a higher saturation density and longer life-span than untreated normal cells (text-fig. 1); the long life-span permits the cells before aging to undergo the many alterations required for neoplastic changes.

Recently, Rhim et al. (*19*) reported morphologic changes in AC fibroblasts when treated with MNNG for 7 days; however, the MNNG-treated cells produced no tumors in athymic nude mice (*19*). The AC cells morphologically transformed by 4-NQO (*18*) and MNNG in our experiments also did not form tumors in the subcutis of nude mice. The results of Rhim et al. and our results suggest that additional changes in carcinogen-treated AC cells are required for malignant transformation as described by Rhim et al. (*19*). Inoculation of AC cells treated with the tumor promoter TPA alone into the anterior chamber of the eye of a nude mouse produced a tumor (*7*). TPA enhanced the frequency of viral transformation of AC fibroblasts (*9*) and also increased the colony-forming frequency of the chemically transformed AC cells in soft agarose (data not shown). The tumorigenicity of AC cells treated with both carcinogen and TPA remains to be tested.

Although the tumorigenicity has not yet been confirmed, the morphologically altered AC fibroblasts possess th markers of transformation previously demonstrated in many cases of chemical transformation of other animal cells. Determination of the cellular factor that enhances the morphologic transformation of AC fibroblasts is required to elucidate the genetic factor in this syndrome.

Carotid Body Tumors in Humans: Genetics and Epidemiology[1]

Dilys M. Parry,[2] Frederick P. Li,[2,3] Louise C. Strong,[4] J. Aidan Carney,[5] David Schottenfeld,[6] Ronald R. Reimer,[7,8] *and* Seymour Grufferman[9,10]

ABSTRACT—Genetic factors in the etiology of carotid body tumors (CBT) were sought in a medical record review of 222 histologically diagnosed cases at 12 U.S. medical centers. Patients in the series, which had a marked female predominance (146 females:76 males), usually developed tumors between the fourth and seventh decades of life (mean, 44.7 yr). In 16 patients who also had other extra-adrenal paragangliomas, suggesting a multiple primary tumor syndrome, CBT were diagnosed significantly earlier (mean, 35.4 yr; $P<0.01$). The occurrence of thyroid cancer in 5 other patients appeared to be excessive. Familial CBT was recognized in 16 patients from 13 affected families, including 9 newly ascertained kindreds. Compared with nonfamilial lesions, familial CBT tended to develop bilaterally (38% vs. 8% unilaterally) and at slightly earlier ages (41.6 vs. 44.9 yr). CBT was reported to occur in an autosomal dominant pattern in some families and within sibships in others; relatives were not examined for confirmation. The familial findings are generally consistent with a two-step mutation model of the development of hereditary and nonhereditary CBT; apparent deviations from the model might be clarified with additional data on this rare neoplasm.—JNCI 1982; 68:573–578.

The carotid bodies are paraganglia that probably develop from cells of the embryonic neural crest (*1*). Genetic etiology of CBT is suggested by familial occurrence of the neoplasm (*2*), and environmental influences are implied by the tumors' increased frequency at high altitudes (*3*). In this collaborative study, we examined hospital charts of 222 CBT patients to further clarify the etiologic role of host and environmental factors.

MATERIALS AND METHODS

The CCPDS is a program of uniform registration of patients at comprehensive cancer centers in the United States. In 1977, 10 member institutions of CCPDS, the National Cancer Institute, and the Cleveland Clinic Hospital agreed to provide hospital records for an epidemiologic study of patients with CBT (table 1). Because CBT is uncommon, the institutions were asked to retrieve data on all cases regardless of admission date. The wide variation among institutions in the cases contributed reflects differential case accrual as well as uneven success in chart retrieval. The records of 222 patients with CBT diagnosed through histologic examination were examined for sex, race, birthplace, birth date, past medical and family histories, date of onset of tumor manifestations, signs and symptoms at presentation with tumor, date of histologic diagnosis, extent of tumor, treatment, and outcome. Information concerning possible genetic or environmental risks was not uniformly recorded in the hospital charts.

Student's *t*-test was used to determine the statistical significance of the difference in mean ages. For patients with metachronous bilateral tumors, age at diagnosis was that for the first tumor. The chi-square test was used to evaluate differences in proportions of patients with bilateral tumors. The binomial proportion of females in a variety of tumor categories (total No. of females in category/total No. of patients in category) was compared to an expected proportion of 0.50 by means of the normal approximation (*4*). Data on many of the patients from the Mayo Clinic, Memorial Sloan-Kettering, and the Cleveland Clinic were included in previous articles (*5–9*).

RESULTS

The ages at diagnosis of CBT ranged from 11 to 83 years (mean, 44.7 yr; text-fig. 1). In most patients, the presenting sign was a slowly enlarging mass first noted an average of 5 years before histologic diagnosis (range, 0–47 yr). Unilateral CBT was diagnosed in 199 patients (90%) at an average age of 45.3 years and occurred with equal frequency in the left and right neck in both sexes. Bilateral tumors were diagnosed in 23 patients (10%) at an average age of 39.4 years, 6 years earlier than the age for unilateral tumor diagnosis ($P>0.05$).

Distribution of the 222 CBT patients by sex and race is shown in table 2. The proportion of females, 146 of 222 patients or 0.66, differed significantly from the expected value of 0.50 (table 3). Females predominated at all ages, particularly in the sixth and seventh decades of life (text-fig. 1). The excess of females was significant among patients

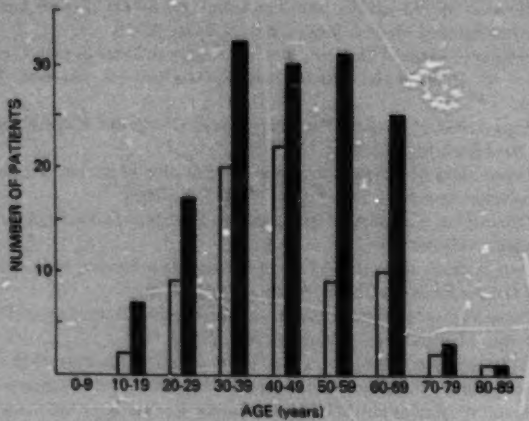
with unilateral tumors, but not among those with bilateral disease (table 3).

Malignant CBT, manifested as local invasion or metastasis, was found in only 9 patients, all with nonfamilial unilateral lesions: 4 had metastases to adjacent lymph nodes at the time of initial tumor excision, 4 had proved metastases in bone, and 1 had metastases in the lung. In these patients, the intervals between initial tumor diagnosis and metastatic disease ranged from 6.1 to 8.2 years.

Of 222 CBT patients, 37 (17%) developed other primary tumors (table 4). PG were diagnosed in 16 patients (#1–16), including 5 with bilateral CBT, and 4 with a third primary neoplasm. The PG occurred most frequently in the jugular body. The mean age at diagnosis of CBT in patients with PG was 35.4 years as compared with 45.4 years in patients without PG ($P<0.01$). The other 21 patients (#17–37) developed 26 additional tumors that were chiefly skin cancers and adenocarcinomas, including cancer of the thyroid gland in 5 females. The proportion of females among patients with PG did not differ significantly from 0.50, whereas females were in excess among patients with other primary tumors (table 3).



TEXT-FIGURE 1.—Age at diagnosis in 10-yr intervals for male and female CBT patients. □ = males, ■ = females.

Sixteen patients in this series (7%) were members of 13 families with CBT reported in 2 persons or more (text-fig. 2). Relatives were not clinically examined. A relative was considered to have had CBT only if this diagnosis was explicitly stated in the proband's chart. Families I–IV were reported previously (*6, 10, 11*); the remaining 9 were newly ascertained. Family IX was separately reported (*12*). Bilateral tumors were present in 6 of the 16 familial cases (38%) in our series, compared with 17 of 206 cases (8%) without a family history of CBT ($P<0.005$); 2 of the familial CBT cases also had PG. On the average, CBT was diagnosed 3 years earlier in familial than in nonfamilial cases (41.6 and 44.9 yr, respectively; $P>0.05$). There was no excess of females among the 16 histologically confirmed familial cases as compared to the significant female predominance among all nonfamilial cases (table 3). The lack of female predominance was also seen among all cases of CBT reported in the 13 families (22/45 affected individuals=0.49, $P>0.80$). CBT in multiple generations in 3 newly identified families (V–VII) involved vertical transmission through affected males. The 6 other new families were reported to have multiple affected siblings with apparently unaffected parents, including affected sib-pairs in family VIII who were first cousins.

Diverse medical conditions other than neoplasms were reported in individual CBT patients. Prior chronic cardiac or respiratory disorders were noted in 20 patients (table 5); this frequency (20/222 patients=9%) did not seem excessive for the patient age distribution, but the data may be incomplete and were not suitable for further analysis. Renal stones in 14 patients (6%) were of interest because hyperparathyroidism is associated with several neural crest tumors (*13, 14*). No other diseases were in striking excess. Most of the patients lived in the Midwestern or Northeastern United States and their histories showed no domicile at high altitudes, but their physicians may not have sought this information.

DISCUSSION

Epidemiology

This collaborative study confirmed previous reports that most CBT are unilateral without preference to side (*6*) and occur primarily during middle age (*6, 12, 15*). Although prolonged hypoxia resulting from chronic pulmonary dis-

ease or high-altitude exposure was suggested previously as a cause of carotid body hyperplasia (*16*, *17*) and neoplasia (*18*), evidence for it could not be obtained from our patients' fragmentary residential or medical histories. CBT were more frequent in women in this study, whereas diverse sex ratios were reported in smaller series in the literature (*6*, *15*, *19*). The twofold excess of women among nonfamilial cases in our study (137 females:69 males = 1.98) was less striking

TEXT-FIGURE 2.—Pedigrees of 13 families with CBT. *Numbers under symbols* are ages in years at CBT diagnosis. The pedigrees of families I, II, and IX have been modified from the published versions (*2, 11, 12*). P = diagnosis by pathology; all others diagnosis by medical history only. □, ○ = unaffected males and females, respectively; ◧, ◐ = males and females, respectively, with unilateral CBT; ■, ● = males and females, respectively, with bilateral CBT; ▨, ◍ = tumor laterality not specified; ◇ = sex not specified; □, ○, ◇ with internal numbers = multiple siblings; * = patient in present series.

than the female predominance reported in residents at high altitudes in the Peruvian Andes (19 females:3 males), Mexico City (37 females:3 males), Bolivia (12 females:1 male), and Colorado (10 females:2 males) (*3, 20–22*). The female predominance consistently observed among the collaborating institutions suggests that females generally have increased susceptibility to CBT which may be further accentuated by prolonged hypoxia (*3, 16–18, 20–22*).

Multiple Primary Tumor Syndromes

Many of our patients developed multiple primary tumors. In particular, PG in 16 CBT patients cannot be explained by chance. Embryologically, all paraganglia including the carotid body are thought to develop from the neural crest (*23*). Concurrent development of these tumors in patients in this and previous reports (*6, 24–26*) may, therefore, be the consequence of a common susceptible progenitor cell (*23*). CBT have also been described in association with other disorders of neural crest-derived tissues, including pheochromocytoma and neurofibromatosis (*27, 28*). These conditions were not recorded in the present series; concurrence of CBT and PG in the absence of pheochromocytoma and neurofibromatosis may represent a distinct neuroendocrine syndrome.

Among our patients with CBT and PG, 4 had third primary tumors (table 4). Patient #13, who also had multiple birth defects, was 1 of 15 patients previously reported with this unusual tumor syndrome (*9*). The tumors in patient #14 may represent a variant of this disorder. In patient #15 medullary carcinoma of the thyroid gland, a tumor not described before with CBT, is a component of the neural crest-derived multiple endocrine neoplasia syndromes, types II and III. Epidermoid carcinoma of the lung in patient #16, a 59-year-old cigarette smoker, appears distinct from these genetically associated cancers.

The second primary tumors in CBT patients *without* PG included adenocarcinomas of the thyroid gland in 4 women and an unspecified thyroid cancer in a fifth (table 4). The thyroid cancers were not attributable to prior radiotherapy because only 1 of the women received such treatment. Biased ascertainment of conditions in structures in proximity to the carotid bodies might explain the finding. Concurrence of thyroid gland tumors with PG (including CBT) has been reported in other patients and in dogs (*3, 29, 30*). Among the other tumors found in CBT patients without PG, most were adenocarcinomas (breast, endometrium, and bowel) and skin cancers, the most common neoplasms in elderly women.

Genetic Implications

The aggregation of CBT in 13 families, including 9 newly ascertained kindreds, suggested that genetic factors were of

[b] Bilateral CBT.
[c] Family history CBT.

etiologic importance in this rare neoplasm. As is characteristic of heritable tumors (*31*), the familial cases had a high frequency of bilateral and multifocal (CBT with PG) disease, an approximately equal sex ratio among affected individuals, and evidence of vertical transmission. In addition, patients with PG developed CBT at a relatively early age.

Knudson et al. (*31*) developed a two-step mutation hypothesis to explain the existence of hereditary and nonhereditary forms of several tumors. According to the hypothesis, in hereditary cases the first mutation is prezygotic and may be dominantly inherited; tumors develop only in rare somatic cells that sustain a postzygotic second mutation. In nonhereditary cases, tumors develop only when both mutations occur postzygotically in a single somatic cell line.

The two-step hypothesis was initially developed for retinoblastoma and other malignant embryonal tumors from a review of data on age at diagnosis, multiplicity of tumors, and familial tumor patterns (*31*). Similar data on CBT were collected in the present study. The predominance of bilateral and multifocal tumors within affected families and evidence of vertical transmission were consistent with a two-step mutation hypothesis. However, in contrast to expectations based on this model, ages at diagnosis of hereditary and nonhereditary CBT were not significantly different. This phenomenon had been observed previously for this tumor (*12*). Other aspects of our data also were not compatible with the simplest form of this hypothesis. Females predominated among patients with nonfamilial tumors, as compared with an expected frequency of 0.50 seen among familial cases in this series and in the literature (*2, 12*). Furthermore, female predominance approached significance in the combined category of nonfamilial bilateral and/or multifocal CBT (19 females/27 patients = 0.70; $P>0.06$). In the two-step hypothesis, nonfamilial bilateral or multifocal tumors are considered to result from new prezygotic heritable mutations and thus are expected to occur equally in both sexes. Finally, although consecutive affected generations were seen, the most frequent familial pattern was of multiple affected siblings with unaffected parents.

A consistent excess of females with CBT among institutions participating in this study suggested that the sex distributions of our patients reflected real differences in tumor susceptibility. The data on family history were much less reliable: Inasmuch as relatives were not examined, we likely underestimated the number of affected individuals within our families as well as the total frequency of familial disease. However, the familial patterns were similar to those described for 16 CBT families and for hereditary retinoblastoma (*2*). Retrospective family studies of both of these tumors suggested large numbers of asymptomatic gene carriers and apparent low gene penetrance. However, follow-up study of the progeny of familial and bilateral retinoblastoma probands indicated a highly penetrant autosomal dominant gene (*32*). Similar data on the progeny of CBT probands are not available.

Several explanations have been proposed for the departure of familial tumor patterns from that expected for autosomal dominant inheritance (*31*). Decreased gene penetrance could account for some unaffected gene carriers. Parental gonadal mosaicism could produce multiple affected siblings in the absence of an affected parent. Malignant embryonal tumors in distant relatives with unaffected common ancestors have been attributed to the lethality of the tumors in affected gene carriers and the survival advantage of the rare unaffected carrier. However, such selection is unlikely to be a significant factor in a benign tumor such as CBT that develops in middle age. This familial pattern could also result from cancer-associated chromosome deletions in offspring of balanced translacation carriers, as reported for familial Wilms' tumor and retinoblastoma (*33, 34*).

Hermann (*2*) applied the delayed mutation model of Auerbach (*35*) to explain the variety of familial patterns seen in both CBT and retinoblastoma. Both this and the two-step hypothesis of Knudson et al. (*31*) involve a two-phase mutational process, but the events involved in delayed mutation may relate only to the initial step of the Knudson hypothesis. In the Auerbach hypothesis, a labile genetic change (premutation) associated with a normal phenotype is transmitted through unaffected carriers. The premutated allele may revert to the normal allele or undergo further change (telomutation) associated with a high risk of a tumor phenotype. Telomutation in a germinal cell would produce affected offspring with unaffected parents and transmission of a highly penetrant autosomal dominant gene in subsequent generations. Telomutation in a target somatic cell would produce an affected individual who would transmit the premutated allele through unaffected carriers. Among 16 CBT pedigrees, Herrmann observed that the tumor frequency among offspring of affected females was lower than that predicted for autosomal dominant inheritance. Our additional pedigrees are noncontributory in this regard inasmuch as no affected woman had offspring. Preferential occurrence of somatic telomutation in affected women could account for the apparent lack of tumor in their progeny.

Data from the present study and the literature suggest that CBT occur in heritable and nonheritable forms. The familial form, like that of other hereditary tumors, is associated with a high frequency of bilaterality and tumors of other specific sites, occurs equally in both sexes, and is vertically transmitted in some families. The genetic etiology of CBT can be further clarified through clinical evaluation of obligate gene carriers and asymptomatic members of affected families to detect minimal or occult tumors, prospective study of progeny of affected individuals, and identification of markers of the CBT gene.

Lymphocyte Fluorescence Polarization Changes After Phytohemagglutinin Stimulation in the Diagnosis of Colorectal Carcinoma[1,2,3]

Glenn R. Hocking,[4] Jennifer M. Rolland,[4] Richard C. Nairn,[4,5] Eric Pihl,[4] Alan M. Cuthbertson,[6] Edward S. R. Hughes,[7] *and* **William R. Johnson[7,8]**

ABSTRACT—A lymphocyte fluorescence polarization test that measures reactivity to phytohemagglutinin (PHA) has permitted discrimination of a majority of patients with colorectal carcinoma from noncancer individuals. The test involves separation of two lymphocyte fractions from 20 ml venous blood on a modified leukocyte separation gradient, incubation with PHA for 45 minutes, addition of fluorescein diacetate, and analysis of change in fluorescence polarization. Of 19 colorectal patients tested preoperatively, 13 had a positive stimulation index, 3 a zero index, and 3 a negative index. Of 7 patients with other malignant neoplasms, a positive value was obtained in 6 and a negative value in 1. Of 14 patients with other diseases, a negative value was obtained in 9, zero in 3, and positive in 2. Of 31 normal donors a negative value was obtained in 27, zero in 2, and weak positive in 2. This rapid test promises to develop into a useful cancer-diagnostic method, and elucidation of its biological basis should identify a new cancer marker.—JNCI 1982; 68:579–583.

Fluorescent probes reveal early changes in lymphocytes after stimulation with antigen or mitogen (*1*), and this offers a feasible screening immunoassay procedure for diagnosing and monitoring of cancer patients. Kreutzmann et al. (*2*) and Pritchard et al. (*3*) reported fluorescent probe assays for lymphocyte response to short-term stimulation with PHA, which distinguished cancer patients from patients with other diseases and from healthy people. This assay is based on a method developed by Cercek and Cercek (*4*), in which decreased fluorescence polarization of intracellular fluorescein was shown by a fraction of normal donors' lymphocytes but not cancer patients' lymphocytes stimulated with PHA. Pritchard et al. (*3*) modified the technique to include separation of lymphocytes into two zones with the use of a Ficoll–Triosil gradient of carefully controlled density. For normal donors, the less dense fraction of lymphocytes responded to PHA better than the denser fraction, whereas the converse was found for cancer patients.

Our results from a preliminary series of cases provide confirmatory evidence of the usefulness of the double-zone fluorescence polarization technique in the detection of colorectal cancer.

MATERIALS AND METHODS

Patients and healthy donors.—Blood samples were obtained from 38 patients with histopathologically confirmed colorectal carcinoma (19 cases postoperative), and 7 patients with other cancers (1 case postoperative), as detailed in table 1, 14 patients with other diseases (table 2), and 31 healthy donors (table 3).

To satisfy ourselves about the objectivity of the tests, we examined "blind" without knowledge of the clinical status blood samples from all patients.

Blood lymphocyte separation.—Venous blood samples (20 ml) were collected from patients and control donors into three 10-ml "Vacutainer" tubes (#6484; Becton, Dickinson & Co., Waltham, Mass.) containing 143 IU lithium heparin. Up to three different blood samples were analyzed conveniently in 1 day. If necessary, blood was stored up to 24 hours at room temperature before use. Lymphocyte separation was performed essentially as described by Cercek and Cercek (*4*) and modified by Pritchard et al. (*3, 5*). Monocytes were removed by incubation with 0.1 g iron carbonyl powder, and lymphocytes were separated on a Ficoll 400 (Pharmacia, Piscataway N.J.)–Triosil 440 (Nyegaard & Co., Oslo, Norway) gradient (density, 1.081 g/cm^3 at 25°C; osmolality, 320 mosmol/kg) by centrifugation at 1,100×*g* at the interface for 25 minutes at 25°C. We divided the interface cells into two fractions by collecting 2 ml in an automatic pipette with the tip held approximately 2 mm above the cell layer (zone 1) and 2 ml with the tip held 2 mm below the cell layer (zone 2). Only occasionally did the interface cell layer appear as two distinct bands; whether or not this occurred, the same method of collection of the upper and lower zones was adopted for all blood samples. Usually, from a 20-ml blood sample, there were about 5–15×10^6 cells in zone 1 and 2–5×10^6 cells in zone 2. Because of the smaller cell numbers in zone 2, replicate experiments were not often feasible with this fraction. The cells of each zone were washed twice with 0.85% saline, once with DPBS (*6*) by centrifugation at 400×*g* for 5 minutes, and finally resuspended in DPBS at a concentration of 1–3×10^6 lymphocytes/ml.

Lymphocyte stimulation with PHA.—Aliquots (0.25 ml) of

ABBREVIATIONS USED: FDA=fluorescein diacetate; DPBS=Dulbecco's phosphate-buffered saline; PHA=phytohemagglutinin.

lymphocytes from both zones were each incubated with 50 μl PHA (GIBCO, Grand Island, N.Y., reconstituted with distilled water, and diluted 1:5 with DPBS) at 37°C for 45 minutes.

FDA substrate solution.—A stock solution of 10 mg FDA/ml (Riedel-de Häen, Seelze-Hannover, Federal Republic of Germany) in Aristar grade glacial acetic acid (British Drug Houses, Poole, England) was prepared weekly. Fresh FDA substrate solution was made for each experiment by adding 10 μl FDA stock solution to 100 ml DPBS and by transferring 25 ml of this solution to 75 ml PBS to which 0.08 g NaCl and 0.03 g Na_2HPO_4 had been added. The substrate solution had a final osmolality of 330 mosmol/kg (pH 7.4) and was stored in a light-proof container at room temperature.

Fluorescence polarization measurement.—Control or PHA-stimulated cells were resuspended by drawing in and out three times a 21-gauge hypodermic needle attached to a 1-ml tuberculin syringe. Aliquots (0.25 ml) of the resuspended cells were mixed with 3 ml FDA substrate solution and transferred in a 1-cm quartz cuvette to a Perkin-Elmer MPF 44A spectrophotometer (Perkin Elmer Corp., Norwalk, Conn.). The spectrophotometer was used as described by Cercek and Cercek (*4*) except for the addition of a half wave plate (HNCP 37; Polaroid Corp., Cambridge, Mass.) in front of the excitation polarizer. Polarization values were determined (*4*) for zone 1 and 2 cells, unstimulated and PHA-stimulated, where possible in duplicate. The percentage reduction in mean polarization after PHA stimulation was calculated for zone 1 and 2 cells, and the difference between these (zone 2−zone 1=stimulation index) was determined for each case.

In table 3, results for normal individuals for whom repeat tests were made are shown. For cases #67 and 85, repeat values were obtained for two separations on the same day. For case #60, the stimulation indices were obtained for the same blood collection, one sample was separated and analyzed immediately, the other was separated and analyzed 24 hours later. Remaining repeat values were obtained for blood samples taken at intervals of 1 week to 6 months.

RESULTS

The correlation between stimulation index and clinical status is shown in text-figure 1. For colorectal carcinoma patients, preoperative blood samples from 13 of 19 cases gave a positive index, and 3 cases gave zero (table 1). The significance of the 3 false-negative cases is not known, but we are testing a larger series of patients to investigate the relationship between tumor stage, differentiation, and stimulation index. Of the 19 postoperative blood samples, the tumor recurrence in case #20 agrees with the positive index, while in case #22, the negative value may reflect successful treatment of a small recurrence detected 10 months previously. Three patients tested before and after surgical excision of tumor showed decreased values postoperatively. Eleven of 16 other cases tested postoperatively had a negative index, and the possible prediction of tumor recurrence by a positive index in cases #23 and 24 awaits further investigation and follow-up.

Of 7 patients with other cancers, 6 gave a positive index. We have no explanation for the negative value for case #45, but the possible effect of certain drugs on lymphocyte reactivity has not yet been established. Again, in case #44 the index decreased postoperatively.

In a small series of 14 patients with other diseases (table 2), there were two false-positives. One of these (case #46) is undiagnosed but is suspected of having a preclinical lymphoreticular cancer. The chronic inflammatory disease ulcerative colitis was associated with a negative index in 7 of

TEXT-FIGURE 1.—Fluorescence polarization changes after PHA stimulation: Stimulation indices for 38 patients with colorectal carcinoma (19 preoperative, 19 postoperative; ● recurrence confirmed), 7 patients with other cancers, 14 patients with other diseases, and 31 normal individuals.

[e] Retested 1; 3 days post operation; stimulation index, 0 and, 0.

10 cases, a zero in 2 others, and a low positive in 1 other. Again, the possibility of preclinical cancer in this positive case will be followed up.

Testing of normal donors' blood lymphocytes (table 3) revealed a negative stimulation index in 27 of 31 cases and a zero value in 2 others. The two false-positive values were low, and for one of these retesting gave a negative index. None of the results seem to be age related, though the preponderance of young adults in our normal controls is a parameter that will be examined fully in our ensuing field trial of the test.

Polarization values obtained in a typical experiment are shown in table 4. In this experiment, duplicate unstimulated zone 1 polarization values differ by 2.3% from the mean. For the experiments of the present series, the variation of replicate polarization values from the mean was 0–9%, with an average variation of 3.2%. Only rarely was a variation greater than 9% obtained, and when this occurred, the experiment was regarded as technically unsatisfactory and was excluded.

DISCUSSION

A good correlation has been demonstrated between the results of the fluorescence polarization test and clinicopathologic diagnosis. Overall, there were only four false-negatives in 26 cases of cancer tested preoperatively, and four false-positives in 45 cases of nonmalignant disease or normal donors. Despite the lack of age matching in this preliminary series, the negative values of cancer patients tested postoperatively is a strong indication that the stimulation index is not age related. This conclusion is also supported by the results of Pritchard and co-workers (Personal communication).

The variation observed in repeat test results of individual normal donors is greater than that observed by Pritchard et al. (Personal communication), which may be due to relative technical inexperience with the method. Nevertheless, all the repeat values were negative. Conversion to negative or zero values 24 hours or more after tumor removal in the 3 cases tested suggests that absence of tumor cells restores normal lymphocyte reactivity. Presumably, the tumor exerts a direct or indirect effect on the blood lymphocytes which is detected by the probe assay. The possible diagnostic use of nonreversal to negative postoperatively indicating residual tumor is being explored, as is the use in follow-up testing of reversal of negative to positive values which indicate tumor recurrence. The nature of the tumor factor responsible for the effect on patients' lymphocytes is not yet known, but the technique should provide a means for its identification and thus of a new tumor marker.

Comparison of polarization values obtained for normal donors and cancer patients suggests that for samples from cancer patients, reactivity of zone 1 cells is decreased and for zone 2 cells is increased. Bater and Pritchard (*7*) found no difference in total cell number distribution on the gradient, between cancer patients and normal donors, which suggests that cancer is not associated simply with a shift in density of PHA-responding cells.

The cell type concerned in the observed fluorescence polarization changes has not yet been identified, and it may well be that more than one subclass participates in the response. Ørjasaeter et al. (*8*) reported that the responding cells in his lymphocyte fraction (density <1.077 g/cm^3) are the T-lymphocytes. In our own studies we have identified T-lymphocytes as the major component in both zones 1 and 2, whether from cancer or noncancer samples (Rolland JM, Nairn RC, Hocking GR, et al.: Manuscript in preparation). The indications so far are that the different behavior of the two zones and the difference between cancer and noncancer are likely to be functions of altered distribution and activity of T-cell subsets. Analysis of polarization changes in separated lymphocyte subpopulations requires larger volumes of blood than may reasonably be obtained from most patients studied. An alternative approach requiring smaller blood samples is suggested by the experiments of Udkoff et al. (*9*), who have distinguished a cell population showing decreased polarization by single cell flow cytometry. This system should permit elucidation of the major reactor cell type by correlation with surface markers and functional assays.

The changes in PHA-stimulated zone 1 lymphocytes detected by fluorescence polarization have been suggested to be due to mitochondrial changes (*10*). Whatever the explanation of the phenomenon, it has been confirmed as cancer

diagnostic by several others (*11–15*). Two groups (*16, 17*), however, were unable to distinguish cancer patients from normal subjects by this test. According to Cercek and collaborators in correspondence (*18–20*), this problem was attributable to "stray-light" artifacts in polarization measurements and an inability to isolate the density-specific lymphocyte subpopulation; however, this explanation is contested by Preece et al. (*21*) and Bagshawe et al. (*22*) in correspondence replies.

We believe that standardization and greater precision of several technical procedures should increase the reproducibility of this test. In particular, improvements could be made in standardization of collection and storage of blood samples, in separation of cell fractions, and in raw data analysis (by direct spectrophotometer–computer linkup). We are currently attempting to refine the test in these various ways to establish its potential for practical diagnosis of primary and recurrent cancer. The elucidation of the biological basis of such a diagnostic test is likely to yield a new cancer marker, and perhaps, of more fundamental significance, to lead to better understanding of cancer and lymphoid cell interactions.

Prevalence and Correlates of Anticipatory Nausea and Vomiting in Chemotherapy Patients [1,2,3]

Gary R. Morrow [4,5]

ABSTRACT—Forty-seven of 225 (21%) consecutive cancer patients were found to experience nausea and/or vomiting prior to a chemotherapy treatment. Multivariate examination of demographic and clinical characteristics showed patients with anticipatory side effects to report more severe posttreatment emesis, to report their most severe posttreatment nausea as occurring later after treatment, and to be more likely to be taking cisplatin than patients without anticipatory side effects. Seventy percent of the patients with anticipatory nausea and/or vomiting attributed the side effects to a psychologic etiology.—JNCI 1982; 68:585–588.

In addition to causing marked disruption to the functioning of cancer patients in their daily activities, nausea and vomiting have been linked to such further treatment problems as postoperative wound dehiscence, dehydration, psychologic depression, and perhaps most importantly, risk of noncompliance with cancer therapy (*1, 2*). As cancer chemotherapeutic treatment regimens have become more complex with multidrug combinations and increasing dosages spread out over longer periods of time, potential problems resulting from nausea and vomiting side effects have become more prominent. Unfortunately (and unlike other situations resulting in these disagreeable side effects), symptom control by antiemetic medication may be incomplete (*3–5*).

Among the wide variations of nausea and vomiting behaviors associated with chemotherapeutic agents are those of patients who have been observed to show nausea and often vomiting in anticipation of chemotherapy treatments; although there have been anecdotal reports of chemotherapy-related ANV, the phenomenon has received little systematic study (*1, 6*). We examined both the incidence and potential correlates of ANV in chemotherapy patients.

METHODS

Subjects.—We studied 227 consecutive chemotherapy outpatients from three separate hospitals of The University of Rochester Cancer Center. All patients were assessed for ANV during their fourth treatment cycle. Clinical experience plus data from a pilot study indicated that patients who experience anticipatory side effects develop them prior to their fourth treatment course.

Data.—Potential correlates of ANV were examined from three general areas: demographic variables, clinical variables, and (for those patients experiencing ANV) self-reports of what they thought was causing the anticipatory side effects.

Demographic characteristics recorded were age, sex, marital status, race, and whether or not the patient had previous chemotherapy, radiotherapy, or surgery before entering their present course of treatment.

The type and number of drugs taken were recorded. A clinical judgment on potential emetic properties of each of 53 chemotherapeutic drugs in active use within the clinic was made before the study. An emetic score from 0 (no emetic property) to 4 (maximum emetic) was assigned each drug by the cancer center pharmacist and nurse clinician.

Pretreatment and posttreatment nausea and vomiting were assessed by a self-report questionnaire. As with other behaviors (*6–8*) both nausea and vomiting were seen as having three distinct topologic elements: frequency, severity, and duration. Questions were asked of each of these elements for nausea before treatment, vomiting before treatment, nausea after treatment, and vomiting after treatment. Frequency for each of the nausea and vomiting time frames was assessed by a four-point scale from "during or after every treatment" to "never." Patients were asked to fill in the number of hours that the nausea or vomiting generally lasted. The severity of the response was assessed on a six-point scale from "very mild" to "intolerable." A six-point scale from "during treatment" to "more than 24 hours after treatment" was scored when the nausea or vomiting was most severe.

Those patients found to experience nausea and/or vomiting before treatment were asked, "Why do you think you have the nausea and vomiting side effects in anticipation of treatment?" Their verbatim answers were recorded.

RESULTS

Prevalence

Of the first 227 patients, 2 refused the questionnaire. Thus a total of 225 responses were evaluable. Of the 225 patients, 47 (21%) reported experiencing ANV before a chemotherapy treatment.

ABBREVIATION USED: ANV=anticipatory nausea and/or vomiting.

Rosenthal in implementing this study is greatfully acknowledged. Ms. Jacque Waight typed the manuscript.

Univariate Comparisons of Demographic and Clinical Characteristics

Univariate comparisons of potential differences between patients who experienced ANV and those who did not on demographic and clinical variables are shown in table 1. The group experiencing ANV was found to be significantly younger than those patients who did not (Student's t-test=−3.33; $P<0.001$). No statistically significant differences were found for sex, marital status, race, and whether or not the patient had previous chemotherapy, radiotherapy, or surgical treatment for their disease (χ_1^2s=0.01–1.46; P-values, not significant).

The taking of only two drugs (singularly or in combination) was found to be associated with patients experiencing ANV: dactinomycin (Fisher's exact probability test: $P<0.009$) and cisplatin (Fisher's exact probability test: $P<0.001$). Patients experiencing ANV took an average 2.5 (±1.1) chemotherapy agents as compared with an average of 2.0 (±1.0) chemotherapeutic agents for the group not experiencing ANV ($t=3.27$; $P<0.001$). The average emetic potential of drugs taken was found to be significantly higher ($t=2.56$; $P<0.01$) for the group experiencing ANV than for the patients not experiencing the phenomenon. No significant differences were found in susceptibility to motion sickness.

TABLE 1.—*Univariate comparisons between patients with and without anticipatory side effects*

Characteristics	Chemotherapy patients with ANV; total, 47[a]	Chemotherapy patients without ANV; total, 178	Significance[b]

[a] No data, —.

[b] NS=not significant.

[c] Mean plus or minus standard deviation.

Posttreatment nausea and posttreatment vomiting were found to be significantly more prevalent in patients with ANV. Patients experiencing ANV also experienced posttreatment nausea with significantly greater frequency than did chemotherapy patients not experiencing ANV ($t_{221}=-5.93$; $P<0.001$). When experienced, the posttreatment nausea was of longer duration (20.5±27.6 vs. 8.6±19.4 hr: $t_{221}=2.78$; $P<0.01$) and greater severity ($t_{221}=6.15$; $P<0.001$) for patients with ANV. The time when posttreatment nausea was most severe was significantly later after treatment for the patients with ANV (4–8 hr) than for other chemotherapy patients (0–4 hr) ($t_{221}=4.27$; $P<0.001$).

A similar pattern in posttreatment vomiting responses was found. Patients with ANV experienced posttreatment vomiting more frequently than did other chemotherapy patients ($t_{221}=-5.44$; $P<0.001$). The duration of posttreatment vomiting was longer (13.4 vs. 2.5 hr: $t_{221}=3.03$; $P<0.01$) and more variable (SD=24.2 vs. 9.2 hr: $F=6.98$; $P<0.001$) for patients experiencing ANV, as were both severity of vomiting ($t_{221}=7.01$; $P<0.001$) and when vomiting was the most severe ($t_{221}=4.71$; $P<0.05$).

Multivariate Comparisons of Patient Characteristics

Not surprisingly, several of the clinical characteristics were found highly intercorrelated. Thus several of the significant univariate comparisons may simply reflect redundant measurement.

To separate out the specific contributions the variables may have had toward ANV, we used two complementary multivariate approaches. The 13 variables found on univariate analysis to significantly differentiate the patients who experienced ANV from those who did not (those variables given in table 1 plus the taking of the two drugs either singly or in combination) were examined in a stepwise multiple regression in which the variables were regressed on the group membership.

Together, the 13 variables accounted for 28% of the variance in group membership. The three variables, self-report of severity of posttreatment vomiting, the taking of the drug cisplatin, and the time when the nausea was the worst, accounted for 26% of the total variance. The remaining 10 variables accounted for 2%.

Patients experiencing ANV might show a different pattern or combination of the characteristics examined than patients without the anticipatory side effects. A 2-group discriminant analysis examined the ability of the 13 characteristics to post hoc "predict" appropriate group membership. All 13 variables were allowed to enter into the prediction equation. A significant differentiation among the 2 groups was found ($\lambda=0.72$; $\chi^2=62.7$; $P<0.001$). Table 2 shows the efficiency with which the discriminant analysis correctly identified case membership for the group experiencing ANV and the group experiencing no ANV. Overall, an 80% accurate classification was achieved based on the 13 variables. Of the 45 patients experiencing ANV, 19 (42%) were correctly classified; of 45 patients, 26 (58%) were not. Of the 157 patients, 143 (91%) who did not experience ANV were correctly classified. Of the 157 patients, 14 (9%) were not. However, prediction of all patients not having ANV would give a 78% (157 of 202) accurate classification.

Physiologic Etiology

The treating oncologist for each patient with ANV was asked if the patient had any physiologic conditions such as *a*) mechanical obstruction of the gastrointestinal system by tumor, *b*) metabolic changes or imbalance, or *c*) brain metastases that would explain the side effects. None of the 47 patients had such a potential contributing factor.

Psychologic Etiology

Two of the patients with ANV reported past psychiatric treatment—in both cases, more than 4 years before being treated for cancer. Whereas an expected range of anxiety, depression, hostility, and other affective responses was shown and reported by patients experiencing ANV, the responses were predominantly reactive and not pathologic.

Patients experiencing ANV were asked, "Why do you think you have the nausea and vomiting side effects in anticipation of treatment?" Verbatim answers were classified into the three categories of "psychologic reasons," "treatment-related reasons," and "other reasons" as shown in table 3. Under psychologic reasons were placed responses that used the words "nervous," "anxious," "tension," "in my mind," "dread," and "no controls." Approximately 75% of 11 males and 75% of 36 females gave answers falling within this category. As can be seen in table 3, there were few differences in the percent of exact words used. Overall, for the combined sample, 33 (70%) of the 47 patients gave answers from which a psychologic etiology could be deduced. Three types of answers were classified into treatment-related reasons: "smell" (that patients appeared to notice in the treatment setting), "pills" (that were taken in preparation for the chemotherapy treatment), and, by 1 person, "distance" (the closer to the clinic the more the patient appeared to experience the side effects). Approximately 25% of the men and 10% of the women experiencing ANV gave a treatment-related reason. Inasmuch as the overall percentage of reasons given in this category was 13%, the numbers in each of the individual classifications are small. Overall, approximately 1 in 5 (17%) subjects gave the answer that they made "no sense" out of experiencing the anticipatory side effects. All of the patients giving this answer were female.

DISCUSSION

Treatment-related variables were found to account for close to one-third of the variance associated with ANV. While an overall "hit rate" of 80% was found for separating patients who experienced the ANV behavior from those who did not on the basis of treatment variables, examination of these results shows significantly greater success in correctly identifying patients who *did not* have ANV rather than those who did. More pronounced side effects following chemotherapy treatment may be necessary but not sufficient for the development of ANV. Experiencing more pronounced side effects following chemotherapy treatment may facilitate or predispose the development of the anticipatory side effects.

The multivariate results require the usual cautious view given any results from multivariate techniques that maximize both true and error variance (*9*). The results require replication. The overall accuracy of approximately 80% (162 hits/202) may or may not prove clinically useful depending on the potential cost of missing a patient with ANV versus the consequences of incorrectly identifying a patient as having a probability of ANV when in fact he or she may not.

No consistent physiologic bases for ANV were found. Potential mechanical obstruction by tumor, gross metabolic changes, and brain metastases that may have influenced the neural strata involved in vomiting were not found. Patients in both groups represented a wide range of both diagnoses and treatment agents.

Patients' self-reported reasons for anticipatory side effects point to a major psychologic role in the phenomenon. And while anxiety and other reactive affective responses were noted, there did not appear to be common diagnosable psychopathology present in the patients with ANV. None of the patients reported nausea as a typical response to previous anxious experiences. Other converging lines of indirect evidence support a contention that ANV is a largely psychologic condition, perhaps the result of learning.

ANV develops only after several administrations of chemotherapeutic agents have been given. Clinical reports and data of this study support the notion that few instances of ANV are seen before a number of administrations of a given therapeutic agent(s), which would be consistent with the development of a learned psychologic response.

The nausea and vomiting seen in anticipation of treatment may be effected by a wide range of eliciting stimuli such as clinic sights and smells, stimuli usually associated with the treatment situation. Situations in which a response is elicited by a stimulus closely associated with a conditioned stimulus may be viewed within the learning theory explanation of stimulus generalization (*10*). The drug cisplatin has a noticeable metallic aftertaste; patients on the drug were found particularly prone to ANV. Children with leukemia have been found to develop a conditioned taste aversion to a distinctive flavored ice cream when it is paired with chemotherapy treatments (*11*).

If it is reasonable to view ANV as a behavioral phenomenon (most likely involving a form of conditioning), then treatment interventions based on learning theory principles may be considered applicable. Several techniques derived from learning theory have been applied to situations thought to be episodes of behaviorally conditioned vomiting. Among these techniques are those of positive practice and overcorrection (*12*), extinction (*13-15*), induced vomiting (*16*), contingent electric shock (*17*), and of perhaps greater efficacy, counter-conditioning procedures (*18-20*). Most of these studies were, unfortunately, single-case studies with little controlled methodology. The argument that these studies provide evidence that ANV is a conditioning phenomenon because conditioning-derived treatments have been shown effective is clearly circular. Nonetheless, the fact that such a wide range of behaviorally derived conditioning procedures has been found effective provides a degree of support for viewing ANV as a conditioned response. A randomized clinical trial examining the potential efficacy of behaviorally derived treatment interventions for the control of these anticipatory side effects is currently in progress (*21*).

Retinoic Acid-Induced Growth Inhibition and Morphologic Differentiation of Human Neuroblastoma Cells In Vitro[1, 2]

Neil Sidell[3, 4]

ABSTRACT—Retinoic acid (RA) induced concentration-dependent morphologic differentiation and growth inhibition in the LA-N-1 human neuroblastoma cell line. Time course studies demonstrated a significant increase in the formation of long neurites in LA-N-1 cultures within 48 hours of RA addition; maximum expression of differentiation occurred at approximately 4 days. This differentiation profile corresponded to a detectable decrease in [^{3}H]thymidine incorporation at 48 hours and complete inhibition of cell growth after 3–4 days. The RA-induced morphologic differentiation and growth inhibition persisted despite removal of the drug. A soft agar assay system showed that RA also inhibited the ability of LA-N-1 cells to form anchorage-independent colonies and induced morphologic differentiation in colonies that did develop. These findings suggest that RA promoted the differentiation of LA-N-1 neuroblastoma cells, resulting in an altered expression of the malignant phenotype.—JNCI 1981; 68:589–596.

The role of vitamin A in the control of cellular differentiation of normal epithelial tissues has long been recognized. Recently, vitamin A and its derivatives (retinoids) have attracted wide attention as antipromoter agents in experimental carcinogenesis and by their ability to alter the expression, tumorigenicity, and growth of fully transformed cells in vitro (*1*). The direct growth-inhibitory effects of retinoids have been demonstrated on a variety of human cell types, including breast, cervical, lymphoblastic, and melanoma cell lines (*2*). Furthermore, retinoids have been shown to inhibit anchorage-independent growth and to stimulate melanogenesis of human melanoma cells in vitro (*3–5*). These effects on melanoma cells prompted this study of the effects of retinoids on human neuroblastoma, a tumor that originates, like melanoma, from tissue of the neurocrest (*6*). Here I report that RA can inhibit the growth, reduce the ability to form colonies in soft agar, and induce morphologic differentiation of a human neuroblastoma cell line. The results of this study support the concept that retinoids can promote the differentiation of certain neoplastic cell types.

MATERIALS AND METHODS

Cell cultures.—The LA-N-1 neuroblastoma cell line was a gift from Dr. Robert C. Seeger, Department of Pediatrics, School of Medicine, University of California at Los Angeles, Los Angeles, Calif. (*7*). These cells were maintained in RPMI-1640 medium (M.A. Bioproducts, Walkersville, Md.), supplemented with 10% heat-inactivated fetal calf serum, 50 IU penicillin/ml, 50 μg streptomycin/ml, and 1 μg Fungizone/ml (complete medium). Cells were grown in a humidified incubator at 37°C in a 5% CO_2 atmosphere. The cells were fed with media twice weekly and subcultured with the use of 0.025% trypsin in a Versene buffer consisting of 0.13 *M* NaCl, 5.4 m*M* EDTA-Na, 7 m*M* $NaHCO_3$, 1.0% glucose, and 2% antibiotic-antimycotic mixture (GIBCO, Santa Clara, Calif.).

Treatment of cells with RA.—all-trans-RA (Sigma Chemical Co., St. Louis, Mo.) was dissolved in ethyl alcohol or dimethyl sulfoxide to a concentration of 10^{-2} *M* and kept as stock solution up to 2 weeks at −70°C under nitrogen. For each experiment, RA was diluted from the stock solution directly into the growth medium so that the final solvent concentration was 0.1% (vol/vol). Control cultures contained 0.1% (vol/vol) solvent alone. This concentration did not affect the plating efficiency, growth, or cell morphology of LA-N-1 cells. For dose-response experiments, RA was diluted in solvent to obtain a series of tenfold decreasing concentrations from 10^{-2} to 10^{-6} *M* and then further diluted 1:1,000 into the culture medium.

Assays for inhibition of cell growth and DNA synthesis.—To examine the effects of RA on anchorage-dependent cell growth, we plated cells (10^5) in T-25 flasks (Falcon Plastics, Oxnard, Calif.) with 5 ml of culture medium. One day after plating, the culture medium was replaced with medium containing RA or with solvent control. The cultures were refed every 4th day with RA or solvent-containing medium until the day of counting, at which time the cells were detached with the trypsin-Versene buffer solution and counted with a hemacytometer. Cell viability was determined by trypan blue exclusion.

To determine the effects of RA on DNA synthesis, we plated 10^3 cells/well in quadruplicate wells of flat-bottom MicroTest plates (M.A. Bioproducts). Culture techniques and retinoid treatment were identical to those of the assay for growth inhibition. At various intervals after adding RA, the plates were pulsed with 0.5 μCi [^{3}H]thymidine/well. After 18 hours' additional incubation at 37°C, the cells were trypsinized and harvested on strips of fiberglass filter paper with the use of a multiple automated sample harvester (MASH-2; M.A. Bioproducts). They were then dried, and the individual samples were counted in a liquid scintillation counter.

LA-N-1 colony formation in soft agar.—The ability of LA-N-1 cells to form colonies in soft agar in the presence of RA

ABBREVIATIONS USED: RA=retinoic acid; CRABP=cellular RA-binding proteins.

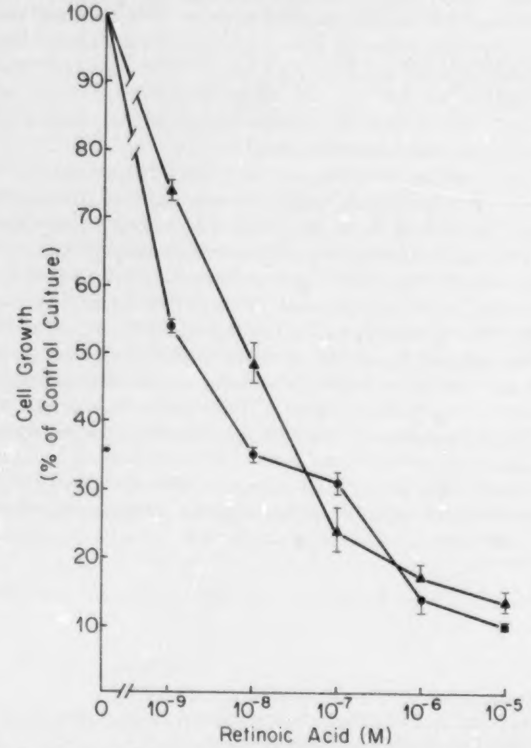
was determined by a modification of the method of Hamburger and Salmon (*8*). Cells (10^5) were suspended in 3 ml of 0.8% SeaPlaque Agar (FMC Corporation, Rockland, Maine) in complete medium containing RA or solvent control and overlaid onto 2 ml 1.5% agar:medium in 60-mm plastic petri dishes (Falcon Plastics). The plates were incubated at 37°C in a 5% CO_2 humidified atmosphere. Colonies consisting of at least 30 cells were counted after 10 days with the use of an inverted microscope.

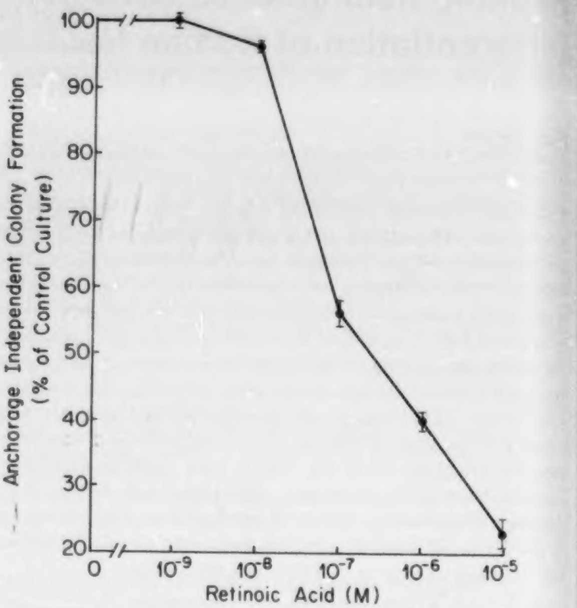
Differentiation curve.—LA-N-1 cells were plated and treated with RA as in the cell growth inhibition assay. Starting with day 1 of RA administration, 200 cells/culture from at least three different regions were examined daily with a phase-contrast microscope. Cells were scored as morphologically differentiated if they possessed one or more processes at least twice as long as the soma diameter, according to the method of Sandquist et al. (*9*).

RESULTS

Dose-response relationship of RA-induced growth inhibition.—The dose-dependent effects of RA on the proliferation of LA-N-1 cells were assessed by cell counts after 7 days and by incorporation of [^{3}H]thymidine after 5 days. Text-figure 1 shows that cellular proliferation as assessed by both criteria was inhibited in a concentration-dependent manner over a range of 10^{-9} to 10^{-5} M RA. In these systems, 50% inhibition of cell growth and [^{3}H]thymidine incorporation was achieved with RA concentrations of 10^{-8} and 2×10^{-9} M, respectively. No decrease in the percentage of viable cells was detected in the treated cultures as compared to that of control cultures.



TEXT-FIGURE 1.—Dose-response curves showing effects of RA on LA-N-1 cell proliferation as assessed by viable cell counts (▲) after 7 days of treatment and by incorporation of [^{3}H]thymidine (●) after 5 days of treatment with RA. Values are the averages ± SE of triplicate and quadruplicate cultures, respectively, from two independent experiments.

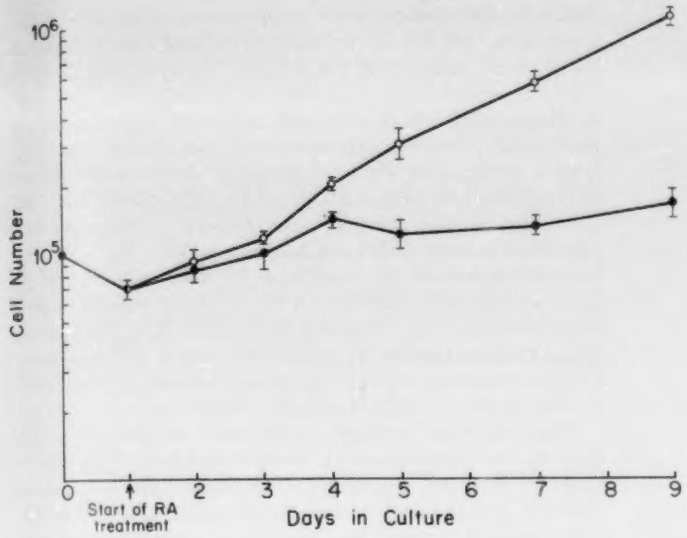


TEXT-FIGURE 2.—Dose-response curve of RA-induced inhibition of LA-N-1 colony formation in soft agar. Values are the averages ± SE of triplicate cultures from two independent experiments.

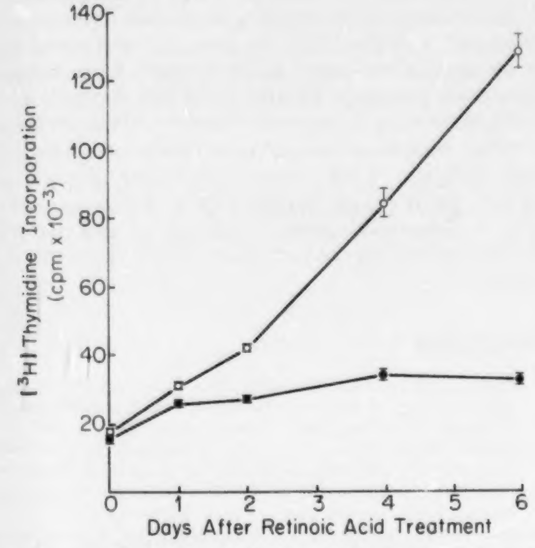
Recent studies of tumor growth in semisolid culture systems have suggested a correlation between anchorage-independent growth and tumorigenicity (*8*). In the present study, the ability of LA-N-1 cells to form colonies in soft agar in the presence of various concentrations of RA was determined (text-fig. 2). When 10^{-5} M RA was included in the agar culture, there was nearly an 80% reduction in the number of colonies that developed. This reduction was dose-dependent, with 50% inhibition occurring at approximately 4×10^{-7} M RA. Moreover, those colonies that developed in the presence of RA were smaller and showed extensive morphologic differentiation as evidenced by the presence of long, three-dimensional, neurite extensions (fig. 1).

Time course of RA-induced growth inhibition.—The growth curves of LA-N-1 cells in the absence and in the presence of 10^{-6} M RA are shown in text-figure 3. The number of viable cells in both the RA-treated and control cultures were similar for 48–72 hours. However, from 72–96 hours, cellular growth in the presence of RA was completely inhibited, with little change in cell count even after an additional 5-day incubation. This inhibition persisted for at least 8 days after the medium was replaced with control medium whether or not the cells were replated in fresh flasks (data not shown). Eventually, clusters of cells developed that had normal growth characteristics.

Text-figure 4 shows the daily [^{3}H]thymidine incorporation of the RA-treated and control cultures. Results were



TEXT-FIGURE 3.—Time course of LA-N-1 cell growth in the absence (○) or presence (●) of 10^{-6} *M* RA. *Each point* represents the mean ± SE of triplicate flasks.



TEXT-FIGURE 4.—Time course of [^{3}H]thymidine incorporation by LA-N-1 cells in the absence (○) or presence (●) of 10^{-6} *M* RA. *Each point* represents the mean ± SE of quadruplicate samples.

analogous to those obtained by direct cell counts except that inhibition of the incorporated isotope could be detected earlier (within 24-48 hr) after the addition of 10^{-6} *M* RA.

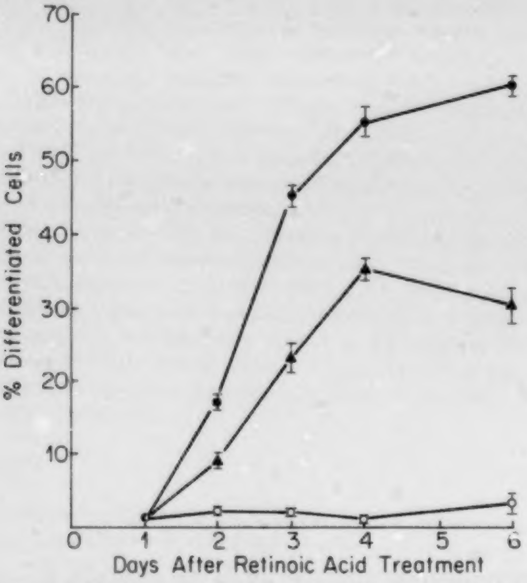
RA-induced morphologic differentiation.—Treatment of LA-N-1 cells with RA caused a dramatic increase in morphologic differentiation as evidenced by the formation of long neurites (fig. 2). The RA concentration that caused maximum increase in the formation of neurites ranged from 10^{-5} to 10^{-6} *M*.

The time course of morphologic differentiation in the absence and presence of two concentrations of RA is shown in text-figure 5. In the presence of either 10^{-6} or 10^{-8} *M* RA, a significant increase in the percentage of differentiated cells could be detected within 48 hours; the maximum extent of differentiation occurred after approximately 4 days of treatment. However, treatment with 10^{-6} *M* RA produced a significantly greater percentage of differentiated cells than did 10^{-8} *M* RA. Moreover, at the lower concentration of RA, the processes were generally not as long as those formed in the presence of 10^{-6} *M* RA.

The morphologic differentiation induced by RA was retained by the LA-N-1 cells in the absence of the drug (fig. 2C). When RA was removed after 5-7 days of treatment at 10^{-5} to 10^{-6} *M*, most cells retained their long processes for at least 10 days. Furthermore, when RA-treated cells were replated with control medium, extensive differentiation remained apparent up to 7-10 days later. This long lag in reversibility of RA-induced morphologic differentiation parallels the persistent growth inhibition observed after removal of the drug.

DISCUSSION

The results of this study demonstrate that RA induces concentration-dependent growth inhibition and morphologic differentiation of the LA-N-1 human neuroblastoma cell line. RA was reported to affect a mouse teratocarcinoma cell line and a human promyelocytic leukemia cell line in a similar manner (*10, 11*). RA-induced inhibition of anchorage-dependent growth of LA-N-1 cells could be detected after 72 hours by cell counts but within 48 hours when assayed by incorporation of [^{3}H]thymidine. The elapsed time before reduction of [^{3}H]thymidine incorporation was observed corresponds to the time after RA treatment before an increase was seen in the morphologic differentiation of LA-N-1 cells. This correspondence is consistent with the reduced rate of DNA synthesis generally associated with a differentiation process (*12*) and supports the contention that true differentiation is occurring. Bottenstein (*13*) reported that morphologic differentiation of LA-N-1 cells also occurs when these cells are grown in serum-free, hormone-supplemented medium. However, no reduction in growth rate was



TEXT-FIGURE 5.—Time course of morphologic differentiation of LA-N-1 cells in the absence (○) or present of 10^{-6} *M* RA (●) and 10^{-8} *M* RA (▲). *Each point* represents the mean ± SE of values from triplicate flasks.

observed under those conditions. The fact that RA was added to the cultures 1 day after plating with no subsequent decrease in cell viability suggests that the effects in our study were not the result of the selection of more differentiated cells due to differences in cellular plating efficiency or RA cytotoxicity.

The growth-inhibitory activity of retinoids has been reported to be reversible in many tumor systems within 48 hours after removal of the drug (*2*, *14*). These reports contrast with the present data which demonstrated the relative irreversibility of RA-induced growth inhibition and morphologic differentiation of LA-N-1 cells. Nonreversible differentiation of human neuroblastoma cells was reported after treatment with cyclic AMP elevating agents (*15*); however, changes mediated by a variety of other agents and culturing in serum-free medium were found to be promptly reversible (*12*). Preliminary experiments indicate that the slow onset of growth of LA-N-1 cells after prolonged RA treatment (>7 days) may be due to a subpopulation of RA-resistant cells rather than to a slow reversibility of the entire population. Further studies are needed to clarify this point.

Recent reports indicate that retinoids can retard anchorage-independent growth of various histologic types of tumors (*3*, *16*). The present study extends these observations to human neuroblastoma by demonstrating that RA reduced the colony-forming ability of LA-N-1 cells in soft agar and promoted morphologic differentiation in colonies that did develop. To my knowledge, this is the first report of a system in which morphologic differentiation can be induced in suspension cultures of neuroblastoma cells. The implications of this RA-mediated phenomenon are presently unknown.

The mechanism(s) by which RA induces morphologic differentiation and exerts its antineoplastic effects on LA-N-1 and other cells has not yet been elucidated. One possibility could be suppression of the activity of endogenously produced growth factors in a manner analogous to retinoid-mediated blockage of the phenotypic cell transformation produced by sarcoma growth factor in rat fibroblasts (*17*). Such a mechanism has been proposed for the RA-induced differentiation of human HL-60 promelocytic leukemia cells (*11*). This or other mechanisms may involve direct interaction with nuclear DNA via binding to CRABP (*18*, *19*). Further support for this hypothesis will naturally depend on the detection of CRABP in LA-N-1 or other neuroblastoma cells. However, the relatively high content of CRABP in other neuroectoderm-derived tumors, such as melanoma (*20*) and retinoblastoma (*21*), make the presence of CRABP in human neuroblastoma a likely possibility.

Thus this report presents a new tumor model with which to study the differentiating activity of retinoids. This system becomes especially appealing when one considers the morphologic, biochemical, and electrophysiologic modes of differentiation that might be evaluated in neuroblastoma cells (*12*). Furthermore, the natural history of neuroblastoma, with its relatively high rate of spontaneous differentiation and regression in vivo (*22*), suggests that this tumor type may be among the most easily "triggered" to undergo maturational processes. In support of this concept, initial experiments testing the growth inhibitory effects of RA on eight other neuroblastoma cell lines indicated substantially greater sensitivity to RA treatment than that observed with other cell types. These results should encourage further studies of the possible role of retinoids as differentiating agents for controlling the malignant phenotype of this type of cancer.

Gaseous Formaldehyde and Hydrogen Chloride Induction of Nasal Cancer in the Rat[1,2]

Roy E. Albert,[3] Arthur R. Sellakumar,[3] Sidney Laskin,[3,4] Marvin Kuschner,[3] Norton Nelson,[3] *and* Carroll A. Snyder[3,5]

ABSTRACT—The carcinogenic response to the combined and separate exposures to formaldehyde (HCHO) and hydrochloric acid (HCl) was investigated in male inbred SD rats. The rats were exposed to gaseous HCHO, 14 ppm, and HCl, 10 ppm, in two experiments. In one experiment the gases were premixed at high concentrations before being diluted in the exposure chamber air to maximize the formation of the carcinogen bis(chloromethyl)ether (BCME). In the second experiment exposure was repeated to HCl and HCHO premixed at high concentrations, and not premixed (to minimize BCME formation), as well as to HCHO alone and HCl alone. The second experiment is being reported on at an interim stage. HCHO alone induced squamous carcinomas of the nasal cavity as did the combined exposures to HCHO and HCl. No carcinogenic response was observed with HCl alone. HCHO accounted for most, if not all, of the carcinogenic activity of the mixture of HCHO–HCl. JNCI 1982; 68:597–603.

The alpha halo ether BCME is a highly reactive industrial alkylating agent (*1*). Studies conducted in this laboratory have shown BCME to be carcinogenic in mice by skin painting (*2*), carcinogenic in rats by sc injection (*3*), and highly carcinogenic in the respiratory tract of rats by inhalation (*4, 5*). Subsequent epidemiologic investigations have shown that BCME is a human carcinogen (*6–8*). It breaks down to HCl and formaldehyde (HCHO). Recent studies have demonstrated that low levels of BCME may be formed by the gas-phase reaction of HCl and HCHO (*9*). Because of the potential hazard from the formation of BCME or other alkylating agents when significant quantities of HCHO and HCl are used in close proximity, a study was done to evaluate the effects of chronic inhalation exposure to a mixture of HCHO and HCl (experiment 1). A second study was done to repeat the combined exposure to HCHO and HCl and to examine the carcinogenic effects of each alone (experiment 2). The complete results of the first study and the preliminary results of the second study are reported here.

MATERIALS AND METHODS

Experiment 1.—Animals: Eight-week-old male inbred S-D rats (Blue Spruce Farms, Altamont, N.Y.) weighing 262±16.1 g were used. Purina Laboratory Chow (Ralston Purina Co., St. Louis, Mo.) and water were provided ad libitum except during exposure periods.

Gas exposure: A group of 99 rats were exposed to the mixture of HCl and HCHO. Groups of 50 air sham-exposed and 50 untreated rats were used as controls. HCHO vapor and HCl gas were mixed at high concentrations before introduction into the inhalation chambers to maximize the formation of BCME. HCHO vapor was entrained in air passing over a slurry of paraformaldehyde (purified trioxymethylene; Fisher Scientific Co., Fair Lawn, N.J.) in paraffin oil maintained at 75–90°C. The HCHO-laden air was directed into a 13.5-liter mixing vessel. HCl was simultaneously metered into the mixing vessel from a tank of compressed HCl 99.0% grade (Matheson Gas Products, East Rutherford, N.J.) with the use of a dual-syringe feed (Modern Metalcraft, Midland, Mich.). Make-up air was introduced into the mixing vessel from a compressed air tank (Linde, Division of Union Carbide Corp., New York, N.Y.) to yield an overall gas mixture flow rate of 4 liters/minute. The effluent from the mixing vessel passed directly into the air intake of the exposure chamber. Since the air flow through the exposure chamber was 300 liters/minute, there was a 75-fold dilution of the effluent from the mixing vessel.

Animal exposures took place in 1.3-m^3 exposure chambers, the details of which have been previously described (*10, 11*). Exposure chamber levels of HCHO and HCl were measured at 0.5-hour intervals, and levels of HCHO and HCl in the reaction vessel were measured twice daily. A chromotropic acid method was used for the analysis of HCHO (*12*), and HCl was measured by titration with sodium hydroxide. To determine BCME, we employed a trichlorophenol derivative technique followed by electron-capture gas chromatography analysis (*13*).

The rats were exposed to gases for 6 hours/day, 5 days/week for life. They were housed in suspended wire cages during nonexposure periods. All animals were observed daily, weighed monthly, and allowed to die naturally or were killed when moribund.

Necropsy and histologic samples: Complete necropsy was performed on each animal, and particular attention was given to the respiratory tract. In the HCHO–HCl-exposed group and the air sham-exposed group, the entire head was fixed in 10% neutral buffered Formalin and then decalcified.

ABBREVIATIONS USED: BCME=bis(chloromethyl) ether; CIIT=Chemical Industry Institute of Toxicology.

[4] Deceased 1976.

[5] We thank the following persons who participated in one or more phases of these studies: Mr. Stephen La Mendola, Dr. George M. Rusch, Dr. Gary Katz, Mr. Martin Erlichman, Mr. Daniel A. Isola, Dr. Virginia Cubberley, Mrs. Helen Ford, Mr. Robin Lindenboom, Mr. Frederick Fennikoh, Mr. Reade Moulton, Mr. Kenneth Magar, Mr. Gordon Cook, and Mrs. D. J. Natalizio.

The head was divided sagittally along the midline. Histologic slides were prepared from each side of the head to display the entire nasal cavity as viewed laterally from the midline, including the nasal turbinates, maxillary turbinates, and the endoturbinates. Histologic sections were also taken from the larynx, trachea, pulmonary lobes, liver, bladder, kidney, spleen, and other organs with gross pathologic alterations.

Experiment 2.—Animals: Nine-week-old male SD rats (Charles River CD) weighing 316±19 g were used. Animal care was the same as in experiment 1. One hundred rats were used in the following 5 treatment groups: *a*) combined exposure to HCHO and HCl where the two gases were premixed at high concentrations before dilution as in experiment 1; *b*) combined exposure to HCHO and HCl where the two gases were not premixed at high concentration but fed separately into the inlet air supply of the exposure chamber; *c*) HCHO alone; *d*) HCl alone; and *e*) air sham-exposed controls.

As in experiment 1, animal exposures were conducted in 1.3-m^3 exposure chambers. HCl and HCHO determinations were made every 0.5 hours during each 6-hour daily exposure. HCl levels were determined as in experiment 1. HCHO levels were determined by the chromotropic acid method used in experiment 1 or by use of an infrared gas analyzer (Miran IA; Foxboro Analytical, South Norwalk, Conn.) at a wavelength of 3.58 µm, calibrated by the chromotropic acid method. No BCME measurements have yet been made at this stage of the study.

Animal observations, weighings, killing, and autopsy procedures were done as in experiment 1, except for the preparation of the head. The decalcified head was cut vertically into four 5-mm-thick slabs, beginning just behind the nostrils and extending back as far as the orbits, including most of the nasal cavity. Histologic sections were obtained from the face of each slab. The tumor data reported here include only nasal lesions in rats that produced grossly evident nasal swelling as in figure 1. The complete pathology on all the animals will be presented in a subsequent report when the experiment is completed.

RESULTS

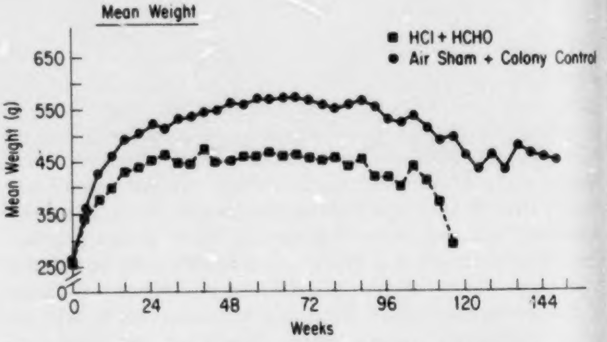
Experiment 1

The average measured gas concentrations in the exposure chamber over the entire experiment were 10.6 ppm HCl and 14.7 ppm HCHO. HCHO levels of 800–1,500 ppm and HCl levels of 5,000–8,000 ppm in the reaction vessel were found to be necessary to maintain the chamber concentrations at nominal levels of 10 ppm HCl and 14 ppm HCHO. To maintain the target level of HCl in the inhalation chambers, an excess had to be introduced to compensate for wall losses, presumably in the tubing and exposure chambers.

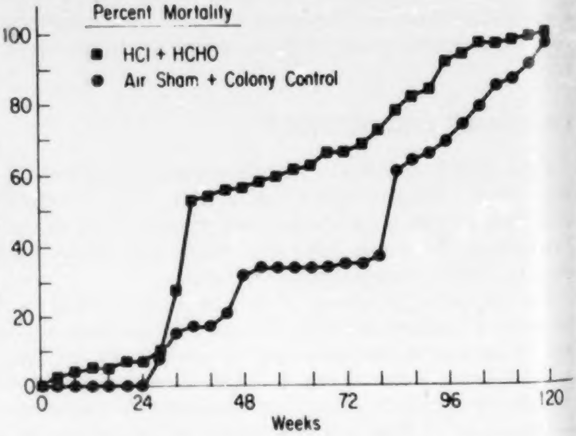
In the determination of BCME, the measured trichlorophenol adducts could have been formed from BCME or chloromethylal. The measured levels of trichlorophenol adducts therefore represent the upper limit of the BCME concentration. A total of 10 determinations were performed. Five determinations were performed 10 months after the exposures commenced, and five were performed 15 months after the exposures commenced. The BCME concentrations in the mixing vessel ranged from 8 to 179 ppb with an average of 75 ppb and a standard deviation of 64 ppb. The BCME levels in the exposure chamber were too low to measure but were estimated on the basis of a 75-fold dilution factor to average about 1.0 ppb.

The weight and mortality curves of the exposed animals are given in text-figures 1 and 2, respectively. In these figures, the air sham-exposed and colony controls are combined. The weight gains in the exposed group were substantially lower than that of the controls. Mortality was low up to 24 weeks, but it increased rapidly in the next 20 weeks and remained higher in the exposed group thereafter. As evidenced by gross and histologic examination, early deaths in both exposed and control rats were due to acute bronchopneumonia. Almost all animals dying later also had bronchiectasis and bronchopneumonia.

As shown in table 1, a high proportion of the exposed rats showed a squamous metaplasia of the nasal cavity that was not found in the control rats. There was also more epithelial hyperplasia and epithelial hyperplasia with atypia in the



TEXT-FIGURE 1.—Growth of 99 rats receiving chronic exposure to the gaseous mixture of 14.7 ppm HCHO and 10.6 ppm of HCl compared to that of the combined group of 100 controls, 50 of which were air sham exposed and 50 of which were untreated (expt 1).



TEXT-FIGURE 2.—Mortality of rats following exposures to HCHO + HCl compared to mortality of the control groups (expt 2).

exposed group than in the controls. Many of the controls showed inflammation of the nasal mucosa, but the severity was much less marked than in the exposed rats. Mucosal changes in the larynx, trachea, and bronchi are shown in table 2. There was a substantial amount of hyperplasia of these mucosa in both exposed and control animals. In exposed rats, squamous metaplasia was more prominent in the nasal mucosa than in the laryngeal, tracheal, and bronchial mucosa.

Of the 99 animals, 28 developed tumors of the nose, 25 of which were squamous carcinomas and 3 of which were papillomas. The temporal pattern of the carcinoma occurrence is shown in the mortality-corrected cumulative incidence curve with respect to elapsed time after the onset of exposure (text-fig. 3). This mortality-corrected cumulative incidence was calculated by the life-table method which consists of calculating the fraction of animals that were alive in successive 4-week intervals and that die of nasal cancer and then obtaining the cumulative fraction of the animals not dying of nasal cancer. From this the cumulative fraction dying of nasal cancer is determined (*14*). The first carcinoma was seen at 223 days, and the mortality-corrected incidence rose steadily thereafter to a level of 77% at 720 days when there were only 3 animals alive. The cancers appeared invariably as a nasal swelling (fig. 1) and eventually caused dyspnea and wheezing. On gross examination, the tumors were opaque greyish-white masses which usually filled the nasal cavity and perforated the nasal bone, infiltrating the surrounding areas (fig. 2). Histologically, all the malignant tumors were squamous cell carcinomas, ranging from moderately to well-differentiated lesions (fig. 3). There were 2 animals dying at 552 and 560 days; both rats had nasal cancers with metastatic lesions in the lungs. In the exposed animals no primary tumors were observed in the larynx, trachea, or the lungs. No tumors were observed in the respiratory tracts of the controls. Nonrespiratory tract tumor incidences are shown in table 3.

Experiment 2

At this reporting the experiment has been in progress for 588 days (19.4 mo). Table 4 shows for the 5 treatment groups the average concentrations of HCHO and HCl, the number of exposures, the percent of survival at 588 days, and the number of nasal cancers. The concentrations of HCHO and HCl were very close to the target levels of 14 and 10 ppm, respectively. Although the exposures were nominally on a 5-day/week basis, there were no exposures on holidays, some shut down days for housekeeping, and occasional generation equipment failures. On the average, the exposures were done for two-thirds of each week, or 4.7 days/week, which was also the case in experiment 1. The animal weights are shown in text-figure 4. There was about a 14% depression in weight associated with the combined exposure to HCl and HCHO and about a 9% depression with HCHO exposure alone; there was no significant loss in the HCl-exposed group. The mortality curves for the various groups are shown in text-figure 5, and the survival at 588 days is given in table 4. HCl exposure had no effect on the mortality rate of 29%. A substantially higher mortality (45–49%) occurred in the combined HCHO and HCl exposures, and an intermediate mortality of 38% was seen after the HCHO exposure alone.

The number of nasal cancers in each group is also shown in table 4. As in experiment 1, on inspection of the rats, all of the histologically confirmed cancers were grossly evident as nasal swellings. No nasal swellings were seen that were not nasal cancers. All of the cancers except one were squamous cell carcinomas. The one exception was an adenocarcinoma which occurred in the combined nonpremixed HCHO–HCl group. There were 12 cancers in the combined premixed HCHO–HCl group, 6 cancers in the combined nonpremixed HCHO–HCl group, 10 cancers in the HCHO group and none in the HCl- or air sham-exposed groups.

The statistical comparisons of the cancer incidences are shown in table 5. The *P*-values by the Fisher's exact probability test for HCHO (P=0.001) and both combined HCHO–HCl exposure groups (P=0.016 and P=0.0002) were statistically significant in comparison with those of concurrent control groups and markedly so in comparison with those of the historical controls ($P=10^{-8}$ to $P=10^{-16}$). There was no statistically significant difference between the cancer responses of the 2 combined HCHO–HCl groups (P=0.12). The mortality-corrected cumulative cancer incidence is shown in text-figure 6. Tumor formation began at 420 days and steadily increased thereafter; only 1 tumor, in the non-premixed HCHO–HCl group, appeared before 420 days. The 2 HCHO–HCl groups when combined had essentially the same slope as the HCHO group, with the premixed HCHO–HCl group having a somewhat higher slope than the HCHO group and the nonpremixed HCHO–HCl group having a somewhat lower slope than the HCHO group. The premixed HCHO–HCl group in experiment 2 had a substantially later time of onset than that in experiment 1 (420 compared to 240 days, respectively) so that the incidence at 600 days was about double that in experiment 1 compared to that in experiment 2 (35 vs. 17%).

DISCUSSION

The results of the combined exposure to HCHO and HCl and HCHO alone are decisively positive for the induction of squamous carcinomas of the nasal cavity. It is clear that up to 84 weeks much of the carcinogenic response is from HCHO, since HCl exposure did not produce any cancers. The premixed HCHO–HCl and nonpremixed HCHO–HCl exposure groups were included in the experimental design to examine the possible effects of BCME arising from the interaction of HCl and HCHO. The introduction of HCl and HCHO separately into the exposure chambers caused these gases to interact at a 75-fold lower concentration than that under the premixed exposure conditions; presumably, there was a correspondingly lower concentration of BCME. With the measured level of BCME in the exposure chambers in experiment 1 at 1 ppb or less, it seems unlikely that BCME alone could contribute much to the tumorigenic response on the basis of the earlier BCME study (*4, 5*). Twenty days of exposure, 6 hours/day at 100 ppb (or a cumulative dose of 2,000-ppb exposure days), produced a 6% incidence of nasal cancer. In experiment 1 all the rats were dead by 100 weeks. With the BCME concentration estimated to be ≤1 ppb, the cumulative dose by 100 weeks

(5 exposures/wk) would have been ≤500-ppb exposure days. Even if the response were proportional to the cumulative dose, which is probably an upper limit, the incidence of nasal carcinomas would be only one-fourth of that observed with 20 exposures to 100 ppb of BCME or 1.5%. The observed nasal cancer incidence in experiment 1 was 25%. The protraction of the BCME exposure over 100 weeks in this experiment compared to 4 weeks in the earlier experiment might be expected to reduce the predicted nasal cancer incidence below 1.5% (*15*). BCME also induced esthesioneuroepitheliomas of the nasal mucosa in contrast to the squamous carcinomas observed in the experiments reported here. Supporting the lack of effect of BCME is the finding in experiment 2 that the tumorigenic responses are about the same for HCHO as occurred with the combination of the two HCHO-HCl groups (text-fig. 6). Nevertheless, in experiment 2 there was about twice the incidence of nasal cancers in the premixed HCHO-HCl group as in the nonpremixed HCHO-HCl group; this difference in tumor response was fairly unlikely on a chance basis (P=0.12). It remains to be seen whether the difference will continue through the rest of the experiment. If so, it may be that mixing the HCHO and HCl at high concentrations does produce an added carcinogenic effect, which, under the conditions of this experiment, counteracts a small suppressing effect of HCl on tumor formation by HCHO.

There are some differences between the carcinogenic responses to premixed HCHO and HCl in experiments 1 and 2. The Sprague-Dawley rats were obtained from different suppliers, and the animals in experiment 2 reached a higher plateau weight and had better survival and only about one-half the mortality-corrected nasal cancer incidence at 84 weeks (35 vs. 17%).

To our knowledge, the results of experiment 2 provide the first confirmation of the carcinogenic response to HCHO in the CIIT study (*16*). The conditions and responses in the two studies were strikingly similar. The exposure concentrations were the same at 14 ppm; both studies yielded squamous cell carcinomas of the nasal cavity. The rat strains, however, were different, the CIIT study involved F344 rats in contrast to the SD rats used here. At 18 months the studies were comparable with respect to the effect of HCHO on weight and mortality; rats in our study showed a 9% weight depression compared to 14% for the CIIT study, and the mortalities at 18 months were 26 and 20%, respectively. The carcinogenic response began earlier in the CIIT study (12 vs. 14 mo), and the number of rats dying of nasal cancer at 18 months was higher (19/100 in the CIIT study and 8/100 in our study). These differences may be due to the different strains of rats.

The results of experiment 2 do not decisively disprove the notion that the carcinogenic response to HCHO is a nonspecific response to irritation, but they do not support it either. The addition of the irritant HCl gas to HCHO did not enhance the carcinogenic response: The nonpremixed HCHO-HCl group had a somewhat lower response than the group exposed to HCHO alone, and the premixed HCHO-HCl group had a somewhat higher response. It is possible that the 14 ppm HCHO by itself was on a plateau of irritation response and that the HCl alone was not tested long enough or at a high enough concentration. A comparison of the nasal mucosal pathology in the various treatment groups will be reported later.

Enhancement of Skin Tumorigenesis by Cigarette Smoke Condensate Following β-Irradiation in Rats[1,2,3]

John F. McGregor[4,5] (with revisions by D. K. Myers)[6,7]

ABSTRACT—The tumor-promoting ability of cigarette-smoke condensate (CSC) has been demonstrated in rat skin after β-irradiation. Skin tumors from male albino Charles River CD rats (outbred Sprague-Dawley descended) were classified into 2 groups: carcinomas and other noncarcinoma tumors. A statistically significant increase ($P<0.01$) in tumor yield occurred after CSC treatment that began 2 months after irradiation. This finding confirmed our previously published pilot observation. Extension of the pilot experiment to obtain data on carcinoma yield and an experiment to observe the effects of CSC treatment beginning immediately after irradiation were performed. When CSC treatment began immediately after irradiation, the yield of noncarcinoma tumors was significantly reduced ($P<0.01$), whereas the carcinoma yield increased but statistically not significantly ($P=0.12$). The increased yield of noncarcinoma tumors is attributed to a significant increase ($P<0.01$) of acute ulceration caused by CSC on recently irradiated skin. The increase in carcinoma yield resulted from an increase in the rate of conversion of noncarcinoma tumors to cancer. Carcinoma yield was also increased by CSC treatment beginning 2 months after irradiation, but the increase was not significant ($P=0.08$). The lack of statistical significance for the carcinoma yields in both experiments may be ascribed to the insufficient number of cancers produced by the treatments. The relative ratios of cancer yields (1.7 and 2.5) did not differ greatly from the 2.2 ratio for the increase of noncarcinoma tumors. The possible relevance of the findings to human carcinogenesis is discussed.—JNCI 1982; 68:605–611.

In a preliminary investigation we observed that CSC treatment of rat skin produced a significant threefold increase ($P<0.01$) in the number of skin tumors induced by β-radiation (*1*). This effect could be attributed to the tumor-promoting action of CSC because tumors were not produced by CSC treatment alone. The applications of CSC were begun 2 months after the irradiation (i.e., about halfway between exposure time and earliest appearance of tumors) when the epidermis presumably contains tumor cells well advanced toward neoplasia. The previous finding was particularly interesting because rat skin is well known for its refractoriness to carcinogenesis by coal tar (*2*) and carcinogenic hydrocarbons (*3*) and to the tumor-promoting action of croton oil (*4*). Thus it seemed important not only to confirm the pilot observation, with extension of the study into the cancerous phase, but also to assess the effect of CSC treatment beginning immediately after irradiation.

Although exposure to ionizing radiation is known to produce cancer in humans and animals, conflicting estimates of the cancer risk may be derived from various interpretations of synergism between ionizing radiation and other agents. For example, a significant increase in lung cancer deaths has been found among uranium miners who were exposed both to radon daughters and cigarette smoke (*5*), and the high yield of lung cancer among fluorspar miners may be related to exposure to radon daughters and to inhalation of mine dust (*6*). Because we are especially interested in the reasons for such increases in cancer incidence, a program was initiated to identify any kind of synergism between ionizing radiation and certain chemical carcinogens in the environment. The present results confirm the tumor-promoting ability of CSC in irradiated rat skin and also suggest that acute ulceration, as a consequence of CSC treatment, is capable of encouraging induced tumors to become malignant.

MATERIALS AND METHODS

Animals.—Male albino Charles River CD rats (outbred Sprague-Dawley descended) were chosen by reason of their susceptibility to skin tumor induction by ionizing radiation (*7*). We avoided using females because the production of mammary tumors could have complicated the interpretation of the results. The rats were about 42 days old when obtained from the supplier, housed 2 per suspended wire cage, and supplied Purina Laboratory Chow and water ad libitum. Gross health examinations and body weights provided evidence that the rats were in satisfactory condition for the treatments.

Radiation.—At about 63 days of age, deep anesthesia was induced in each rat with 62 mg pentobarbital/kg body weight, and the dorsal hair was removed with an Oster electric clipper (size 40 head). The age of 63 days corresponds approximately to the beginning (anagen) of the third hair growth cycle, as determined by the appearance of new hair growth in animals whose hair had been clipped a few days before the experiment started. The anesthetized rat

[7] Thanks are expressed to Dr. F. G. Bock, Roswell Park Memorial Institute, for providing the cigarette smoke condensate and helpful advice; to Dr. N. J. Gragtmans, Dr. J. D. Childs, and Dr. M. C. Paterson of this branch for their constructive criticisms of the manuscript; to Mr. M. A. Jones for technical assistance; and to Mr. B. Ruhnke for performing the biopsies and for his excellent histologic examination.

was then placed inside a specially designed radiation chamber (*8*), and its back was superficially irradiated over a 5×3-cm area.

A flat source of strontium-90–yttrium-90 (140 mCi or 5.2 GBq) emitted β-particles of high energy (2.27 MeV), with a maximum penetration of about 10 mm in tissue. The dose rate at the surface of the skin was about 700 rad or 7 Gy/minute, and the dose measured at the undersurface of the skin was 60% of the surface dose, determined with lithium fluoride Teflon discs (*9*). A single surface dose of 1,600 rad (16 Gy) was used to produce skin tumors.

CSC.—The CSC was prepared from U.S. blended cigarettes (Orchard Park Laboratories, Orchard Park, Buffalo, N.Y.), and a supply on Dry Ice was received monthly. The frozen condensate was dissolved in reagent grade acetone on a 40% weight/volume basis. One application of acetone condensate on skin consisted of dipping a ⅞-inch artist's paint brush about ¼ inch into the material and brushing three downward strokes on shaved skin covering about 4×9 cm. Approximately 128 mg of CSC per application was deposited on the skin. Applications were performed three times a week for 18 months in one experiment and for 12 months in another.

Procedure and comments.—A total of 916 rats were used in two experiments with 10 test groups, of which 9 are shown in table 1. The remaining group served to test nicotine toxicity of CSC before beginning the experiment.

The first experiment was performed to assess the tumor-promoting action of CSC when its applications began immediately after irradiation, i.e., before the potential neoplastic tissue progressed toward neoplasia. The first application of CSC was completed within a few seconds after irradiation. This experiment also attempted to demonstrate that CSC alone (without irradiation) was a complete carcinogen in rat skin and to measure quantitatively the additive versus the synergistic effects. For this purpose, CSC applications were continued both in irradiated and nonirradiated animals for 18 months or about one-half of the maximum life-span of the rat. This time is equivalent to about 35 years in humans. The maximum incidence of bronchogenic carcinoma in human beings occurs after 30–35 years of smoking (*10*), also about one-half of the human life-span. The group sizes were 200 rats for the sequential treatment of radiation and CSC, 100 rats for radiation alone, 100 for CSC alone, and 100 for each of 2 untreated controls. In addition, a separate group of 100 rats received CSC for 12 months after the skin "barrier" (stratum corneum) was removed by a stripping technique, not only to facilitate CSC penetration to the basal layer of cells but also to stimulate cell division (*11*).

The second experiment repeated the pilot study (*1*), with the number of rats increased from 15 to 60 per group, a radiation and acetone control added, and the observation period increased from 8 to 14 months after irradiation. As before, CSC applications began 2 months after irradiation or about halfway through the latent period for first-appearing tumors, at which time the potential neoplastic skin would presumably contain foci of active and dormant tumor cells.

Tumors.—The skin was checked for tumors at monthly intervals from the time of irradiation. A tumor was recorded when it had reached the minimum size of 1 mm. Tumors that regressed from view were not included in the subsequent analysis. Skin tumors were divided into 2 groups: carcinomas and other noncarcinoma tumors. The term "papilloma" is frequently used to describe all types of benign tumors in rodent skin, but it is an imprecise description for most of the exophytic growths observed in the present work, where tumor morphology more often resembled keratoacanthomas than true papillomas (*1*). A detailed description of the morphology of radiation-induced epithelial skin tumors in rats has been given by Albert et al. (*7*). In the present study, all tumors except carcinomas were grouped together for purposes of statistical analysis. We have not attempted to classify them further because it is almost certain that all growths originated from the ectodermal epithelium; thus their exact histogenesis may be of little importance (*12*). Rats with apparent cancers were sedated 1 month after the appearance of cancer, and portions of the tumor were removed for histologic examination; thereafter, death was surgically induced and necropsy was performed to find visible tumors in the organs. Tissues were fixed in 10%

TABLE 1.—*Experimental regimen, survival, and tumor yields*

Treatment		Initial No. of rats	Duration of experiment, mo	Survival, %	Noncarcinoma tumors			Carcinomas		
First	Second				No.	Average	Ratio	No.	Average	Ratio
Expt 1. CSC applied immediately after irradiation										
Radiation	CSC	200	18	51	96	0.94	0.47	30	0.29	1.45
Radiation	None	100	18	35	70	2.00		7	0.20	
CSC	None	100	18	72	1	0.01		0		
Expt 2. CSC applied at 2 mo after irradiation										
Radiation	CSC	60	14	72	112	2.60	1.58	12	0.28	1.64

buffered Formalin and then blocked in wax and stained with hematoxylin and eosin. Basal cell carcinomas and squamous cell carcinomas were identified. Since both of these tumor types are progressively invasive and grossly destructive to the skin, they were grouped together for the analyses in this work. Cancer was verified in a small number of tumors by rapid growth of tissue transplants in the flanks of weanling rats whose immunological system had been suppressed by whole-body irradiation and cortisone treatment (*13*).

RESULTS

In view of one report on the deaths of rats due to nicotine toxicity from CSC (*14*), 36 young rats were treated with CSC over a period of 3 weeks before the start of the experiment. The stratum corneum was first stripped from half this number of animals. No deaths or spastic convulsions were observed from the treatment.

Examination of the data for late deaths revealed that there were markedly fewer deaths among the animals in the CSC groups than among the other groups and that the increases in survival were statistically significant ($P \leq 0.02$) for two of three comparisons (table 2). Although the reason for this difference is not known, most of the deaths in the experiment could be attributed to CMP, a contagious syndrome with the probable etiology of a mycoplasma (*15*).

A comparison of mean tumor numbers at final scoring shows *a*) a reduction in yield of noncarcinoma tumors and an increase in carcinoma yield for CSC treatment beginning immediately after irradiation, and *b*) increases in yields of both carcinomas and other tumors for CSC treatment beginning 2 months following the irradiation (table 1). The data also show an increase in the number of tumors for the skin-stripping treatment, but in terms of absolute numbers this effect is not dramatic enough to be used in the analyses. There was a slight (not significant) reduction in tumor yield for acetone treatment after irradiation.

TABLE 2.—*Statistical comparisons of survival rates between groups with and without CSC treatment*

Treatment	Initial No. of rats	No. of rats dead	Survival, %	*P*-value[a]

1,600 rad + CSC	20	17	72	

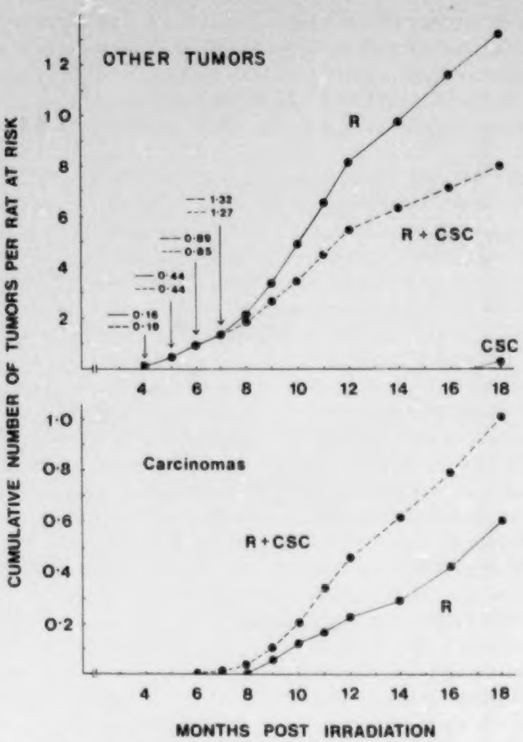
[a] χ^2 test.

[b] CMP "flared up" during this treatment at 14 mo of age for a period of 8 days, killing 22% of the animals.

[c] CMP occurred in ≈4% of the animals.

[d] CMP was first observed at 8 mo of age in 10% of the animals in the radiation group vs. 0.5% ($P<0.001$) in the radiation+CSC group.

[e] CMP was first observed at 7 mo of age in 27% of the animals in the radiation group vs. 14% ($P>0.05$).

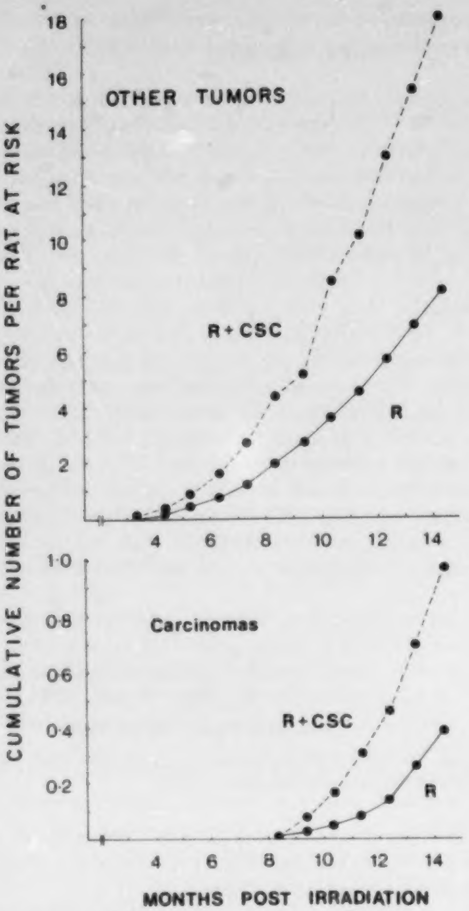


TEXT-FIGURE 1.—Cumulative incidence of tumors after CSC treatment beginning immediately after irradiation (R).

Tumor production is best interpreted by plotting the accumulated incidence of tumors per surviving animal against month of observation. For this, a life table method (*16*) of analysis provided incidence rates unbiased by loss of animals from premature deaths due to unrelated causes or killed because of unmistaken moribundity. The number of tumors scored at the end of 1 month was divided by the number of animals alive at the beginning of the month less half of those that died during the month, and the incidence rates of the successive months were serially accumulated. The clean separation of the curves for the two kinds of treatment make it more convincing that CSC did indeed increase tumor production in three of four comparisons (text-figs. 1, 2). The relative increases [(radiation+CSC): radiation alone] at the final month of analyses were 1.7-fold for carcinomas (text-fig. 1) and 2.2-fold for noncarcinoma tumors and 2.5-fold for carcinomas (text-fig. 2).

An additional benefit of the life table analysis is that it detects the earliest appearance of tumors, i.e., before they have advanced in growth to become recognizable cancers. The times of appearances of noncarcinoma tumors in both experiments, at about 3.5 and 4 months after irradiation, are in reasonable agreement. Carcinomas did not appear until 6–8 months after irradiation (text-figs. 1, 2).

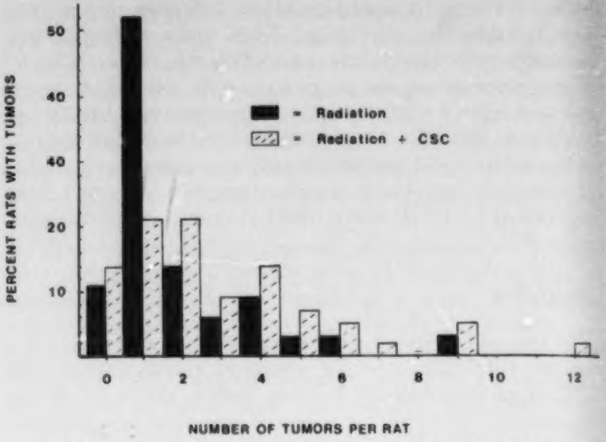
Although the graphic presentations of tumor incidence increases in text-figures 1 and 2 are indicative of tumor-



Text-figure 2.—Cumulative incidence of tumors after CSC treatment beginning at 2 mo after irradiation (R).

promoting action by CSC, they do not provide the needed measure of confidence (*17*) to show a cause-effect relationship. Statistical significance, therefore, was assessed on the life table data at final analysis with a standard error of a difference test (*18*, *19*). A significant increase ($P<0.0001$) in yield of noncarcinoma tumors was obtained for CSC treatment beginning 2 months after irradiation, and nonsignificant ($P=0.125$, $P=0.079$) increases in carcinoma yields were obtained for the simultaneous and sequential treatments with CSC, respectively. This lack of statistical significance is very likely due to the insufficient numbers of cancers produced by the treatments (table 1), since their relative ratios do not differ greatly from that of the other tumors (text-fig. 2).

A skewed distribution is evident when the number of tumors per animal is plotted against percent of animals in each category (text-fig. 3). These data were also analyzed by a conventional chi-square contingency test for proportion of rats with multiple tumors, i.e., 2–12 tumors per rat. There were significantly more ($P=0.021$) multiple tumor bearers in the radiation and CSC group than in the radiation only group.



Text-figure 3.—Distribution of tumors 12 mo after irradiation.

Although the standard error of the means provides an adequate approximation for tests of statistical significance in a variety of distributions markedly departing from normality (*20*), we decided that we should preclude possible bias from the use of a single statistical test with an alternative parametric test that avoids the requirements for tests involving *t*-distribution (*21*). Statistical significance, therefore, was also assessed on the proportions of rats with tumors with the use of a chi-square contingency test (*22*), and data were transformed by the method of Shellabarger (*23*). To compare the total number of tumors in each of 2 groups, the number of animals "at risk" was obtained by multiplying the number of animals in each group by the largest number of tumors observed on any animal in the comparison (*23*). The results of this contingency test ($P<0.001$ and $P\approx0.2$ for effects of CSC treatments on yield of noncarcinoma tumors and of carcinomas, respectively) were in reasonably good agreement with those based on the test of standard error of difference.

DISCUSSION

The results of the present study confirm the earlier observation of tumor-promoting action of CSC in rat skin when the cigarette tar was first applied 2 months after tumor induction by β-radiation (*1*). The present work entails four major points: *a*) the reduction in yield of noncarcinoma tumors for CSC treatment beginning immediately after irradiation, *b*) the later increase in carcinoma yield for the same treatment, *c*) the failure of CSC by itself to produce tumors, and *d*) the relevance of the present findings to human carcinogenesis.

The obvious explanation for the reduction in yield of noncarcinoma tumors would be a loss of potentially neoplastic tissue through death or sterilization of skin. Severe ulceration covered most of the irradiated skin area as a consequence of CSC applications beginning after irradiation, with a maximum effect of 50% rats with ulceration at 21 days, whereas only mild ulceration on only a portion of the irradiated area occurred for the radiation treatment alone, with a peak effect of 27% rats with ulceration at 16 days. Acute radiation exposures of 1,000 rad (10 Gy) or greater are generally required for the induction of skin cancer in both humans (*24*) and experimental animals (*25*), and such high levels of radiation usually lead to acute injury of skin including ulceration, the severity of which increases with dose. It must be emphasized that acute ulceration was not produced by CSC treatment alone or by CSC treatment beginning 2 months after irradiation, although a number of rats were observed with mild dermatitis in the CSC and radiation group. It is thus evident that degenerative changes from radiation were predominant in the skin immediately after exposure to 1,600 rad, demonstrated by greater susceptibility to destruction when CSC was applied, and presumably to injury by other agents.

Whereas the observed reduction of yield of noncarcinoma tumors may be attributed to a loss of potentially neoplastic tissue when CSC was applied immediately after irradiation, the increase in numbers of carcinomas in the same tissue is more difficult to explain. Carcinogenesis may be considered to occur in two stages (*26*), e.g., tumor initiation by β-radiation and tumor promotion by CSC. The modest increase in carcinoma yield with CSC applied immediately after irradiation must be attributed to a third factor and appears to be mostly due to an effect from acute ulceration, rather than to a promoter effect of CSC. This acute ulceration appears to have made the tissues more vulnerable to carcinogenesis. The results obtained with CSC applied immediately after irradiation are comparable in many ways to those observed after exposure of the skin to much higher doses of radiation alone (*7, 8*). In the second instance, more severe ulceration is associated with a suppression of tumor formation, probably due to elimination of the hair follicles in which many of the tumors originate (*7*), but the yield of carcinomas is not necessarily suppressed and may in fact be increased (*8*). The more severe skin damage at high radiation doses results in a shift from basal cell to squamous cell tumors (*7*). The effect of CSC applied immediately after irradiation may be equivalent, at least in part, to an increase in radiation dose.

That carcinomas were not produced in rat skin by CSC alone suggests, in light of the progress in understanding the activation process of polycyclic hydrocarbons since this work began in 1973, that rat skin may possibly be either deficient in appropriate enzymes for epoxidation of CSC hydrocarbons to form ultimate carcinogens or its detoxifying system is highly developed (*27*). It is well established that the tumor initiators in CSC are largely polycyclic aromatic hydrocarbons (*28*). Before this discovery, the earlier workers had demonstrated the refractoriness of rat skin to coal tar (*2, 29*). With the subsequent synthesis of hydrocarbon carcinogens, skin tumors were produced in the rat, but only after exceptionally long latent periods (*3, 30*). Although the refractoriness of rat skin would tend to favor a genetic interpretation, low penetration of the carcinogens because of their molecular size and thickness of skin may be responsible, in part, for the failure to produce skin tumors more readily (*31*). An attempt in the present study to increase penetration of CSC by stripping the stratum corneum (i.e., removing the dead surface layer of skin) once a month did provide some evidence of increased yield of papillomas, but this increase was not dramatic (table 1).

Although data from animal experiments cannot be used as a direct measure of the hazards in human beings, they have greatly increased our understanding of the mechanisms of carcinogenesis and confirmed the epidemiological evidence of cancer induction by occupational and environmental exposures.

In this study we have demonstrated for the first time a response of rat skin to a tumor-promoting agent. This finding is particularly interesting because croton oil, which is the most widely used promoting agent in testing polynuclear hydrocarbons for tumor-initiating activity, suffers from the shortcoming of being species-specific; i.e., it is effective in mouse skin but not in rat, guinea pig, or rabbit skin (*4*). CSC is primarily a tumor-promoting agent with weak carcinogenic activity in the mouse (*32*).

The presumptive role of acute ulceration to produce a higher rate of cancer raises the question of whether radiation followed by some other skin *irritant*, whether or not it is a promoting agent, would enhance carcinogenesis. For example, in chemical carcinogenesis, a synergistic effect occurred for skin tumors of mice first treated with 7,12-dimethylbenz[*a*]anthracene (initiator), then with croton oil, and later with turpentine, which is a skin irritant lacking promoter ability (*33*). More recently, in radiation carcinogenesis, a significant synergistic effect occurred in lung tumors in hamsters after sequential intratracheal instillations of polonium α-radiation and benzo[*a*]pyrene; however, most of this effect could be attributed to a potentiating effect of subsequent instillations of a seemingly innocuous agent, sodium chloride solution, on polonium carcinogenesis (*34*). Thus evidence is accumulating on the importance of a wide range of complex interactions between carcinogens, promoting agents (i.e., incomplete carcinogens), and noncarcinogens, in addition to simple synergism between two carcinogens. Further studies on these interactions are anticipated.

With regard to human carcinogenesis, a World Health Organization chronicle on smoking and disease (*35*) has described the isolation of an enzyme, AHH, from human tissues that metabolizes polycyclic hydrocarbons to form highly carcinogenic metabolites. The activity of this enzyme can be increased by exposure to cigarette smoke and also by taking various drugs in common use, but the extent of its inducibility in an assay with cultured lymphocytes from healthy persons fit a trimodal distribution, i.e., groups of individuals with low, intermediate, and high inducibility (*36*). These different levels of AHH activity have been demonstrated to be under genetic control (*36*). Individuals with genetically high AHH activity are regarded as being at a greater risk of developing lung cancer if they are heavy smokers compared with the risk of individuals with genetically low AHH activity, because those with high AHH activity produce more carcinogenic epoxides that those with low AHH activity (*37*). Some laboratories have experienced difficulty in confirming the reproducibility of the AHH assay and the trimodal distribution. However, animal experiments with inbred strains have demonstrated an association between the genetic locus for AHH and the increased susceptibility toward chemical tumorigenesis (*38*). Thus it is not unreasonable to speculate that cigarette-smoking uranium miners with low AHH activity would be less likely to develop lung cancer from cigarette smoking alone, than those with high AHH activity. The present work with rats has shown that although CSC failed to produce skin cancer, the skin was still susceptible to its tumor-promoting action on the development of radiation-induced tumors. It is possible that the tumor-promoting action of cigarette smoke might also occur in uranium miners with low AHH activity.

APPENDIX: CLASSIFICATION OF SKIN TUMORS PRODUCED IN RATS BY β-RADIATION WITH OR WITHOUT CSC

N. J. Gragtmans, C.V.M., Radiation Biology Branch, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada

For the purpose of this report, epithelial tumors were classified on the basis of their behavior and morphology as either malignant or benign. Upon death of the animal, tumors were submitted for histologic evaluation.

Benign Epithelial Tumors

In general the nodules were well defined, firm, low, and broad based. They were usually keratinizing tumors, originating either from hair follicles or the basal cell layer of the epidermis. Hyperplasia of the follicular cells caused enlargement and fusion of many follicles into one mass. Benign epithelial tumors originating from the basal cell layer appeared as cauliflower-like growth with finger-like processes, made up of a connective tissue core covered by hyperplastic epithelium. However, in both cases the growth was outward, usually with little or no downward invasion. Initially, the mitotic rate of benign tumors was greater than differentiation and keratinization. However, in the later stages the rate of mitosis decreased, followed by differentiation and keratinization of the tumor cells, so that eventually most of the tumor was acellular and consisted of keratin.

Malignant Epithelial Tumors

Most of the tumors in the early stages resembled benign epithelial tumors, but with invasion of subjacent tissues the growth above the skin surface sloughed off, leaving a small ulcerating crater. The crater widened, continued to ulcerate, and frequently became necrotic and infected.

Identification of malignant and benign epithelial tumors is difficult in the early stages, because both seem to have a similar origin and resemble each other histologically. However, tumors were scored grossly when well developed, at which time size, shape, rate of growth, keratinization, sloughing, and ulceration were used as criteria for identification. Upon collection of the tumor, its classification was verified histologically.

Histologically malignant and benign epithelial tumors can easily be differentiated on the basis of keratinization, invasiveness, differentiation, and the frequency of mitotic figures. Malignant epithelial tumors were differentiated from dermally derived, upward-growing tumors (e.g., sebaceous tumors) simply by cell type and histologic arrangement.

Survival of Mouse Mammary Gland Transplants of Normal, Hyperplastic, and Tumor Tissues Exposed to X-Rays[1,2,3]

Leslie J. Faulkin,[4] **Dan J. Mitchell,**[4] **Robert D. Cardiff,**[5] *and* **Marvin Goldman**[6,7]

ABSTRACT—Mouse mammary tissues, including ducts, prelactating lobules, hyperplastic outgrowth lines, and tumors, were exposed to varying doses of X-rays and then transplanted to fat pads of nonirradiated BALB/c mice for study. Estimates of the dose of radiation that would allow survival of 50% of the transplants (SD$_{50}$) were made with the use of probit analysis. Nearly all duct and lobule transplants survived doses of X-rays from 0 to 800 rad. The survival rate declined rapidly following doses above 800 rad, and the calculated SD$_{50}$ was 1,020 and 1,260 rad for mammary ducts and lobules, respectively. The three hyperplastic outgrowth lines tested gave very different results. Hyperplastic line Z5C$_1$ transplants had better than 90% survival at doses up to 1,200 rad and an SD$_{50}$ between 1,200 and 1,600 rad. Hyperplastic line Z5D transplants had an SD$_{50}$ of between 800 and 1,200 rad. Hyperplastic line D$_1$ transplants had a better than 90% survival following doses of 0–600 rad and an SD$_{50}$ between 600 and 800 rad. The survival of tumor transplants was 100% following doses of X-rays up to 1,200 rad; the SD$_{50}$ was in excess of 1,600 rad. The mouse mammary transplantation system can be used to study the direct effect of X-rays on normal, premalignant, and malignant mammary tissues and provides a basis for the study of the radiobiology of mammary tissues.—JNCI 1982; 68:613–618.

The mouse mammary gland was chosen as an animal model to systematically study the radiobiology of mammary glands. The mouse as an experimental model has several advantages: *a*) Mice have short life-spans and, consequently, they reach a tumor-bearing age in months rather than years; *b*) the existence of inbred strains of mice allows transplantation of syngeneic tissue; and *c*) lines of hyperplastic mammary tissue exist with defined characteristics of tumor incidence, morphology, and growth rate available for experimentation and comparison with those of normal tissue (*1–3*). The similarities between the hyperplastic lobuloalveolar lesions in the human mammary gland and those in the mouse mammary gland have been discussed earlier (*4*).

Reports in the literature of the effects of ionizing irradiation on the mouse mammary gland are restricted to the development of mammary tumors after whole-body irradiation. The incidence of mammary tumors, thymic lymphomas, and ovarian, pituitary, and harderian gland tumors was moderately increased following irradiation from an experimental nuclear explosion (*5*). Exposure to 8.8 rad each day for life resulted in mammary tumors in 47%, ovarian tumors in 88%, and lymphoid tumors in 36% of mice (*6*). The increase in mammary tumors following whole-body irradiation could be due to ovarian dysfunction rather than to a direct effect on the mammary gland.

Medina (*3*) has studied several lines of premalignant mammary tissue and reported that administering 450 rad of γ-radiation to the whole body of BALB/c mice bearing transplants of hyperplastic outgrowth lines increased the incidence of mammary tumors. Irradiation of hosts bearing D$_1$ outgrowth increased the tumor incidence from 4 to 23%. When the outgrowth line D$_2$ was used, the incidence rose from 45% for nonirradiated transplants to 61% for those transplants that were irradiated in the hosts. A second generation of transplants taken from the irradiated samples and placed in nonirradiated hosts had 0 and 39% tumor incidence for D$_1$ and D$_2$, respectively. These results again suggest that the increased tumor incidence could be due to the host's being irradiated rather than to a direct effect on the hyperplastic outgrowth.

Several studies of the survival of rat mammary gland cells following irradiation have been reported (*7–10*). In these studies the mammary glands were removed from rats exposed to whole-body irradiation and enzymatically dissociated into single cell suspensions. Then standard numbers of cells were inoculated into nonirradiated host rats. The transplanted cells were judged viable if one or more spheres of cells (or alveoli) were viable in the host 7 weeks later (*7*). A 50% brain homogenate was added to the mammary cell preparation at a 1:1 ratio to reduce the number of cells required for a successful transplant (*8*). No difference was found in the survival rate of irradiated cells from virgin donors as compared to that of cells from pregnant donors (*8*). The transplanted cells responded to the mammotropic hormones secreted by a pituitary tumor transplanted in the host rats and appeared normal in morphology (*7, 9*). The authors (*7, 9*) concluded that this is an effective way to study the direct effect of irradiation on the mammary gland.

The experiments in this paper, like those with the rat mammary gland, were designed to avoid the problem of whole-body irradiation by transplantation of samples immediately after exposure into nonirradiated hosts. The trans-

---

ABBREVIATION USED: SD$_{50}$=dose of radiation that would allow survival of 50% of the transplants.

plants were placed in the inguinal mammary fat pads, which had been freed of host gland. The glands that grew from the transplant could be judged for viability and any change in morphology. By use of small samples of the gland that were excised from the donor with microdissection techniques, specific portions of the mammary gland, e.g., duct or alveoli, could be selected, and associated structures in the fat pad could be avoided. The direct selection of tissue also avoided the exposure of the transplanted cells to the enzymes used to dissociate the mammary cells in the rat experiments and similar ones in the mouse (*11*, *12*). It has been observed in the mouse that dissociation of the cells of the mammary glands of young females from a tumor-susceptible line prior to injection into the fat pad resulted in increased numbers of hyperplastic outgrowths from the transplanted cells (*11*). The transplants of dissociated cells of hyperplastic outgrowth lines developed an increased number of tumors (*12*).

The initial experiments reported here were designed to compare the survival of different types of mammary epithelium following exposure to graded doses of X-ray. The long-term goal is to use the mouse mammary gland transplant system for the study of the radiobiology of mammary tissue.

MATERIALS AND METHODS

Mice.—The BALB/c mice used in this study were either purchased from Simonsen Laboratories, Gilroy, Calif., or bred in our laboratory from strains supplied by Simonsen Laboratories. The mice were housed 5 to a cage, maintained in constant temperature-controlled (22°C) and light-controlled (12 hr) rooms, and given food and water ad libitum.

So that the problems associated with high doses of whole-body irradiation could be avoided, the mammary tissues in this study were irradiated in situ and then transplanted into nonirradiated syngeneic hosts. We prepared 3-week-old female host mice for transplantation by surgically removing the nipple and developing mammary ducts in both inguinal fat pads as previously described (*13*). Each mouse then received two transplants, one in each inguinal fat pad. The tissues were transplanted immediately following the host gland-clearing operation and within 2 hours of exposure of the donor tissues to X-rays.

At varying times following transplantation, ranging from 4 to 12 weeks, some host mice were killed and both inguinal fat pads and a sample of the host gland were removed, placed in fixative, and stained as wholemount preparations (*3*). The wholemount preparations were studied for growth and changes in morphology of the transplant. The transplant was determined to have grown if it had formed end-buds on ductal structures or more than doubled in size from the original transplant, and growth was used as a criterion of survival.

X-ray.—The mice bearing the donor tissues described below were exposed to whole-body X-rays from a 250-kV therapeutic machine. The machine was operated at 250 kV potential, with a current of 15 milliamperes and with the 0.25-mm copper and 1-mm aluminum filters in place. The animals were awake but restrained in a wooden box divided into stalls just large enough for a mouse. The box had a Lucite cover with air holes drilled in it. The target-to-subject distance was 50 cm, giving a dose rate of approximately 100 rad/minute. The Radocon meter was placed in an adjacent stall to monitor the amount of radiation during exposure.

Irradiated ducts.—A total of 150 mice were transplanted with 300 primary ducts from 5- to 6-week-old female mice. In addition to the nonirradiated control group, the donor animals were exposed to X-rays of 250, 600, 800, 1,000, 1,200, or 1,500 rad in a single exposure. The mice bearing the transplants were killed at 4, 6, or 8 weeks post implantation. With allowance made for a few intercurrent deaths and technical failures, the number of fat pads studied is shown in table 1.

Examination of the data for the initial groups in which irradiated ducts were studied led to several modifications of subsequent experiments. First, it was apparent that there were more low-dose groups than were necessary. The subsequent studies concentrated on doses in the range of 400–1,600 rad. Second, it was noted that the time in which the transplants were in the host may not have been long enough to give a reliable result. Consequently, the three time periods were increased to 4, 8, and 12 weeks rather than the 4, 6, and 8 weeks used in the study of the ducts. Increasing the time to 12 weeks emphasized the dramatic difference in apparent viability in the groups exposed to higher doses of irradiation.

Estimates of the SD$_{50}$ were made by means of probit analysis (*14*). Data were insufficient in some groups to perform this analysis. The survival of a transplant is a quantal response; i.e., the transplant survived or it died. Linear regression analysis of log dose on probit of percent loss of transplants relative to that of controls was performed, and the SD$_{50}$ was computed from the resultant linear equation. In the case of the duct transplants it was possible to compute 95% confidence intervals on the regression line, and from these intervals, the 95% confidence limits on the SD$_{50}$ could be computed.

Irradiated lobules.—Lobules were obtained from the mammary fat pads of mice pregnant for 16–18 days. A donor mouse was irradiated with 0 (sham), 400, 800, or 1,200 rad of X-ray. A 1-mm^2 piece of lobule tissue was transplanted into each prepared inguinal fat pad of 15 host mice per dose for a total of 60 mice and 120 transplants. Five mice from each group were killed at 4, 8, and 12 weeks post transplantation for determination of survival rates.

Irradiated hyperplastic lines Z5C$_1$, Z5D, and D$_1$.—The hyperplastic outgrowth lines used in this study had relatively dense lobuloalveolar development and similar growth characteristics. The Z5C$_1$ and Z5D lines were developed in our laboratory from multiparous BALB/cfC3H mice. These hyperplastic lines are in the 14th generation and contain the mouse mammary tumor virus. These new lines were characterized elsewhere (*9*). The virus-free hyperplastic line studied was Medina's D$_1$ series developed in hormone-stimulated BALB/c mice. The D$_1$ hyperplastic outgrowth line has been well characterized and is currently in its 47th generation (*10*).

Both inguinal gland-free fat pads of 15 host mice were transplanted with irradiated hyperplastic tissues at each dose level of 0, 400, 800, and 1,200 rad per outgrowth line. An additional group given 600 rad was added to the D$_1$

study and another given 1,600 rad to the Z5C$_1$ and Z5D studies to identify the amount of radiation necessary to reduce the survival rate by 50%. A total of 150 transplants each for the Z5C$_1$ and Z5D lines and 120 transplants for the D$_1$ line were made. Five mice from each group were killed at 4, 8, and 12 weeks post transplantation for study. Some cages of mice were lost prior to completion of the experiment due to failure of the watering device in the cage.

Tumor.—The tumors used in this study were from the second generation passage of a single tumor that arose in a Z5C$_1$ transplant in generation 10. A single donor tumor for each group was irradiated with 0 (sham), 800, 1,200, or 1,600 rad of X-ray. The control group of tumors and the 800-rad-exposed group were transplanted into 14 gland-free fat pads of 7 host mice each, and the 1,200-rad-exposed and 1,600-rad-exposed groups were transplanted into 16 gland-free fat pads of 8 host mice for a total of 60 transplants. Initial tumor appearance was determined by twice weekly palpation of host animals. When the greatest single dimension of any tumor reached 20 mm, the tumor was surgically removed to prevent it from becoming life threatening and to allow the development of the contralateral transplant.

RESULTS

The viability of mouse mammary gland ducts 4, 6, or 8 weeks after transplantation is summarized in table 1. Viability of the transplants was judged by the examination of wholemount preparations for end-bud formation or an increase in the ducts present in the fat pad. The survival rate was very high for doses of radiation from 0 to 800 rad. At doses greater than 800 rad, the survival rate fell rapidly to 3 or 4% at 1,500 rad. The decrease in the survival rate was linear after 800 rad.

As presented in table 1, there were two replicates at 1,000 and 1,500 rad. An analysis of variance was performed to determine whether the replicates differed in the rate of survival at each of the termination times. Both effects were found to be insignificant ($P>0.05$), and the replicates were pooled for further analysis. Since very few transplants given 1,500 rad survived, visual inspection sufficed to determine that there was no essential difference between replicates given 1,500 rad. Survival of each group relative to that of controls was computed, and from these values the percent loss of survival was computed. The fit of the probit line to the data (for doses of ≥ 800 rad) was quite good. The correlation coefficient was 0.998 ($P<0.01$). The estimated SD$_{50}$ was 1,020 rad with 95% confidence limits of 790–1,070 rad.

The survival of transplants of lobules taken from a pregnant mouse that had been exposed to a single dose of radiation is shown in table 2. Using the criterion of increase in the size of the transplants, we were unable to correctly judge survival at 4 and 8 weeks post transplantation. In all of the irradiated groups, but not in the controls, the number of transplants that survived increased with time post transplantation. Among the transplants in the 800-rad-exposed group, 15% survived at 4 weeks, 50% at 8 weeks, and 90% at 12 weeks post transplantation. In the 1,200-rad-exposed group the survival percentages were 10, 20, and 63 at 4, 8, and 12 weeks after transplantation, respectively. The dissimilarity in the results for the different time periods made totaling the results inadvisable. Thus further analyses of these data were confined to the data obtained 12 weeks post transplantation. Only 2 of the radiation groups demonstrated a depression of the percent takes relative to those of the controls. Following exposure to 800 rad the survival was 90%, and at 1,200 rad the survival was 63% of that observed for the controls. Therefore, the SD$_{50}$ must be greater than 1,200 rad. Using all 3 radiation groups, we estimated the SD$_{50}$ from the probit analysis to be 1,260 rad. The fit of the probit line to these three data points was good ($r=0.993$), but the slope could not be shown to differ significantly from zero at the 5% level of significance. The 95% confidence limits would be extremely broad.

The viability of X-irradiated transplants of the established hyperplastic outgrowth lines was quite different for the lines tested. The results of the transplantation of Z5C$_1$ following various doses of X-ray are presented in table 3. Survival of all transplants was seen in the control group and in the 400-rad-exposed group at 4, 8, and 12 weeks after transplantation, and there appeared to be little heterogeneity in survival among the three time periods tested. Some transplants did not survive in the 800-rad-exposed group,

[b] No significant difference existed between the replicates, and the totals were combined.

but the survival rate was up to 97% following 1,200 rad for the total of all time groups. The survival rate dropped to a mere 3% when the dose of radiation was 1,600 rad. The data are not sufficient to do a probit analysis; the SD_{50} exceeded 1,200 rad and was less than 1,600 rad.

The survival of transplants of line Z5D is shown in table 4. There was very little heterogeneity of results in the various times post transplantation, and the results for the treatment groups were summed. The survival of the transplants in the control and 400-rad-exposed groups was 89%; it was 67% in the 800-rad-exposed groups. There were no surviving transplants in the 1,200-rad-exposed and 1,600-rad-exposed groups. For the Z5D hyperplastic outgrowth line, the SD_{50} was greater than 800 rad and less than 1,200 rad.

Transplants of irradiated D_1 hyperplastic outgrowth lines had a survival rate of 100% in the 0-rad-exposed group, 92% in the 400-rad-exposed group, and 90% in the 600-rad-exposed group (table 5). When the amount of X-ray given the donor was raised to 800 rad, the survival rate dropped to 2 of 30 transplants (or 7%), and only 2 of the 40 transplants exposed to 1,200 rad were viable. The SD_{50} was between 600 and 800 rad.

[a] Number of transplants viable/number of transplants studied.

The viability of pieces of mammary tumor transplanted to the fat pad following irradiation is shown in table 6. The number of tumors that could be palpated of the total number of tumors transplanted are reported for radiation doses of 800, 1,200, or 1,600 rad as well as in the nonirradiated controls. In the control group, 6 of the 14 transplants were palpable 10 days after transplantation. The number of palpable tumors increased each period until all 14 were palpable 30 days after transplantation. When the transplanted pieces of tumor received 800 rad of X-ray, the first tumors were not palpable until 15 days after transplantation. The number of tumors increased to 12 of 14 transplants palpable 25 days after transplantation. The remaining 2 transplants did not develop into palpable tumors during the remaining 25 days of the experiment.

In the group exposed to 1,200 rad of radiation, the first palpable tumors occurred 20 days post transplantation. The number increased to 13 of 16 transplants palpable by 25 days after transplantation and continued to increase and reached 100% by 45 days after transplantation. The transplants that received 1,600 rad of X-ray were slower to develop the first palpable masses; by 25 days post transplantation, only 5 of the 16 transplants could be detected. The number palpable increased during each 5-day interval until 11 of 16 were detected by 40 days after transplantation. The maximum number of tumors developing in this group by 50 days post transplantation when the experiment was terminated was 11 tumors of 16 transplants (or 69%). The SD_{50} for tumor transplants was greater than 1,600 rad.

DISCUSSION

The purpose of these experiments was to compare the effects of irradiation on normal, premalignant, and malignant mammary tissues. Using survival as the response criterion, we accomplished our purpose by establishing dose-response parameters for the various tissues. Wholemount preparations of the mammary outgrowths were used to judge survival, which was considered to be any increase in the size of the transplant. For comparison of one tissue with another, the SD_{50} was calculated or estimated from the data.

More than 90% of the nonirradiated normal duct and lobule transplants survived (tables 1, 2) and showed growth by the 4th week post transplantation. Increasing doses of radiation on the normal tissues resulted in fewer apparent survivors at 4 and 8 weeks post transplantation. The results when lobules were studied were dependent on the time that these transplants spent in the hosts; a higher proportion of survivors were usually detected at the later time points. We are studying the apparent retardation in growth rate with increased radiation dose and will report our findings later. The estimates of the SD_{50} for the two normal tissues were similar; the SD_{50} was about 1,020 rad for duct transplants and about 1,250 rad for lobule transplants (table 7). Nearly 100% of all duct and lobule transplants survived lower doses of radiation until a critical level was reached, followed by a steep decline in survival. These features also resemble the survival curves developed for normal rat mammary epithelium (*8*).

The premalignant mammary outgrowth lines used in these experiments are morphologically hyperplastic and were derived from hyperplastic alveolar nodules similar to nodules found in human mammary dysplasias (*4*). The radiosensitivity of the outgrowth lines studied has demonstrated a surprising diversity, although these lines are similar in morphology and growth rate. The $Z5C_1$ was much more radioresistant than were the normal tissues; the SD_{50} was between 1,200 and 1,600 rad. The Z5D line had an SD_{50} between 800 and 1,200 rad, like that of the normal tissues. By contrast, the D_1 tissue was more radiosensitive with an SD_{50} between 600 and 800 rad. The differences in the radiosensitivity of the three outgrowth lines probably reflect the biological variations in hyperplastic tissues. These observations emphasize our inability to generalize about the radiobiology of premalignant mammary tissue. Rather, the range of possible events will have to be defined by observations on a variety of hyperplastic lines. The D_1 outgrowth line is free of exogenous mammary tissue virus, and the $Z5C_1$ and Z5D lines are infected and express viral antigens (*1*). Although we do not believe that mammary tumor virus infection plays a role in the relative sensitivity of the mammary tissue, we are now examining additional outgrowth lines to study this possibility.

The tumor tissue appeared to be more radioresistant than either normal or premalignant mammary tissues. We were able to conduct the tumor experiments with fewer animals by palpating the fat pads to determine growth rather than periodically killing a number of animals. Consequently, the results of the tumor experiments are presented in a different format. However, a comparison of the tumor group 30 days post transplantation with a comparable normal or hyperplastic group 4 weeks post transplantation illustrates the differences. For example, 44% of the tumor transplants receiving 1,600 rad survived at 30 days after transplantation. No other group had significant survival at this level of radiation.

The experimental conditions described in this paper provide for the comparison of direct radiation effects on different types of mammary tissues. The use of the mammary transplantation system for the determination of the direct effect of X-rays on normal and premalignant mouse mammary tissues can provide the basis for the systematic study of the radiobiology of mammary tissues.

Bile Acids: Effects on Absorption of 1,2-Dimethylhydrazine and 7,12-Dimethylbenz[*a*]anthracene in the Colon of the Rat and Guinea Pig[1,2]

Richard C. Rose, *Ph.D.,*[3,4] *and* **David L. Nahrwold,** *M.D.*[5]

ABSTRACT— The specific effects of bile acids as cocarcinogens were investigated. Absorptions of [^{14}C]7,12-dimethylbenz[a]anthracene, [^{14}C]dimethylhydrazine ([^{14}C]DMH), and [^{3}H]inulin from loops of colons from outbred Sprague-Dawley rats and Hartley guinea pigs were determined. In each animal absorption of one carcinogen and inulin was studied in one control loop and in an experimental loop containing either deoxycholic acid (DOC) or chenodeoxycholic acid (CDOC). DOC had a more pronounced effect on increasing loss of carcinogen from the intestinal lumen than did CDOC. This role of bile acids was consistent with their known effect of increasing intestinal permeability. Less carcinogen remained in the colon mucosa when DOC was present in the intestinal lumen. Although [^{14}C]DMH was absorbed more rapidly from the intestinal lumina of guinea pigs than from those of rats, the rat accumulated more of the carcinogen in the intestinal mucosa and liver.—JNCI 1982; 68:619–622.

Epidemiologic observations have provided correlations between dietary habits and the incidence of colorectal cancer in various populations (*1*). Dietary risk factors include high beef and fat consumption. Explanations for these findings have been sought in various animal models for carcinogenesis, including a DMH model in rats. These studies support the finding of carcinogenic effect of high-fat diets and suggest that consequent increased excretion of bile acids may contribute to colon tumor formation (*2–4*). An association has been noted between colon cancer incidence and elevated concentrations of fecal bile acids in humans (*5, 6*).

Despite the above observations, no specific effects of bile acids on the colon have been noted that account for their role as cocarcinogens. The possibility has not been tested that bile acids might alter uptake or metabolism of carcinogens by changing the structural and functional characteristics of the intestine through their detergent and other properties. Such a role might be possible in view of the known effects of bile acids on separating components of the epithelial cell membranes (*7, 8*) and disrupting the gastric mucosa (*9*) with consequent alterations in epithelial permeability properties.

This study was undertaken to determine whether bile acids increase absorption of a water-soluble carcinogen (DMH) and a carcinogen of low water solubility (DMBA). DMH is used as a substituted hydrazine representative of compounds known to be derived from rocket fuels, tobacco, and edible mushrooms (*10*). Entry of each carcinogen into an epithelium of the gastrointestinal tract must precede its carcinogenic action. Absorption of each carcinogen was compared with absorption of the biologically inert polysaccharide inulin. Results were obtained on rats, which are quite sensitive to the carcinogens used, and on guinea pigs, in which the carcinogens produce fewer tumors. The effect of a secondary bile acid (DOC), which is thought to be responsible for contributing to tumor formation (*11*), was compared with the effect of a primary bile acid (CDOC). In each animal, absorption of one carcinogen and inulin was studied in a control loop and in a paired experimental loop containing bile acid.

MATERIALS AND METHODS

Male outbred Sprague-Dawley rats weighing 300–350 g were obtained from Charles River Breeding Laboratories, Wilmington, Mass., and male Hartley guinea pigs weighing 500–600 g were obtained from Dutchland Laboratories, Denver, Pa. Both species were maintained on normal feed prepared by Charles River Breeding Laboratories.

Guinea pigs and rats were anesthetized with Penthrane (methoxyflurane). A midline abdominal incision was made and two adjacent colon segments were isolated with silk ties, with care being taken not to interrupt the blood supply to the isolated tissue. A small incision was made at each end of the segment and the loop was washed with warm, physiologic buffer. Tubing 3 cm in length was secured into each end of the loop and two ties were placed 3 cm apart to separate the loop into two approximately equal lengths. The bowel was replaced in the abdominal cavity, which was closed with the tubing ends exposed. Body temperature was maintained with a heat blanket and heat lamp. The proximal and distal loops were used alternately for exposure to bile acids.

The test solution in DMH studies was physiologic buffer with 1 μCi [^{14}C]DMH/ml (0.13 m*M*) and 10 μCi [^{3}H]inulin/ml. Experimental loops contained, in addition, 10 m*M* CDOC or DOC. Buffer consisted of 142 m*M* NaCl, 1.2 m*M* $MgCl_2$, 0.9 m*M* $CaCl_2$, 1.5 m*M* KH_2PO_4, and 4.2 m*M* K_2HPO_4 (pH 7.2). [^{14}C]DMH and [^{14}C]DMBA were pur-

chased from New England Nuclear Corp, Boston, Mass.; both were at least 97% pure by the manufacturer's analysis.

Because of the low solubility of DMBA in buffer, this carcinogen was delivered as 1 μCi/ml (10 μM) in a 3% solution of methyl cellulose in buffer. The appropriate test solution (0.5 ml) was injected into each loop for a period of 10 minutes. The colon was removed and both loops were opened, rinsed briefly in cold buffer for removal of adherent radioactivity, and weighed. Tissues from DMH studies were extracted overnight in 0.1 N HNO_3, which was shown to remove at least 98% of both ^3H and ^{14}C activities. Tissues from DMBA studies were extracted first for 12 hours in acetonitrile to remove [^{14}C]DMBA and then in 0.1 N HNO_3 to remove [^3H]inulin. Aliquots of each sample were assayed for radioactivity with appropriate corrections made for counting efficiency. At the end of the test period, samples of liver (≈1 g) and blood (3 ml, by heart puncture) were obtained. Radioactivity was extracted by a method similar to that used for extraction of colon tissue. Statistical evaluations were made with Student's t-test.

RESULTS

The results (tables 1, 2) indicate that during the 10-minute test period approximately 94% of the inulin remained in the intestinal lumen of control loops during DMH studies and 86% remained during DMBA studies. This small difference, which is not statistically significant, might be attributed to the 3% methyl cellulose-buffer test solution used in DMBA studies. There was a tendency for increased loss of DMH, DMBA, and inulin from the lumen of loops that contained bile acids. This finding reached statistical significance only in DOC studies.

Tables 1 and 2 also show the amount of DMH, DMBA, and inulin extracted from the colon tissue calculated as a percentage of the total ^{14}C or ^3H injected into each intestinal loop. The results are also expressed on the basis of wet weight of each loop. Accumulation of DMH and DMBA in the tissues was reduced by DOC but usually not by CDOC. This result was generally true whether the percentage of DMBA and DMH in colon tissue was calculated on a per-loop basis or on the basis of wet weight of the intestinal tissue. The guinea pig absorbed DMH from control loops faster than the rat did ($P<0.01$) but accumulated less of the carcinogen in the colon tissue ($P<0.05$).

Limited information can be derived from the amounts of DMH extracted from liver and blood. Because liver and blood sample were common for control and bile acid loops, the most meaningful treatment of data is a comparison of [^{14}C]DMH and [^3H]inulin between rat and guinea pig. The data (table 3) indicate that the blood or liver [^3H]inulin did not differ significantly between animal species. However, rat blood had significantly less [^{14}C]DMH than did guinea pig blood, and rat liver accumulated significantly more [^{14}C]DMH than did guinea pig liver.

Bacterial dehydroxylation of CDOC into lithocholic acid and other compounds in the colon loops would make it difficult to separate the effect of CDOC from that of metabolites. The extent of metabolism in colon loops in vivo was evaluated by thin-layer chromatography (*12*). No significant modification of bile salts due to the action of colon bacteria was detected.

DISCUSSION

Both epidemiologic observations and laboratory experiments have indicated that diets high in fat are associated with colon tumors. Inasmuch as the appearance of bile acids in the intestinal lumen is associated with increased tumor formation (*11, 13*), it appeared that diets high in fat might result in tumors by causing release of bile into the intestine. We have evaluated the possibility that bile acids increase absorption of carcinogens in the colons of the rat and the guinea pig. Absorptions of a fat-soluble carcinogen (DMBA) and a water-soluble carcinogen (DMH) were studied. The hypothesis was evaluated in rats, which develop tumors in response to DMH and DMBA and in guinea pigs, which are less sensitive to these carcinogens. The secondary bile acid DOC resulted in increased loss of DMBA and DMH from the intestinal lumina of the guinea pig and the rat. This finding is indicative of an increase in permeability of the intestine, which probably results from dissolution of protein (*8*) or phospholipid (*7*) from the cell membrane. Loss of inulin from the lumen was also increased by DOC. This observation suggests that the effect of bile acids is not specific for carcinogens but generally reflects what is known about the actions of these detergents on biologic tissue (*14, 15*) and about the resultant increased permeability to a large variety of compounds.

The amount of inulin found in the colon tissue was generally increased by bile acids in DMH studies, which indicates that increases in tissue permeability result in additional tissue spaces becoming available to inulin. The absence of this effect in DMBA studies suggests that the presence of 3% methyl cellulose protects the tissue against this alteration; the explanation for this protection is not apparent from the present studies.

While DOC increased the amount of inulin in colon tissue, it significantly reduced the amount of DMH and DMBA in tissue. No firm explanation can be given for this observation, but perhaps in loops having DOC rapid loss of carcinogen from the tissue occurs during the wash procedure due to damage of the mucosal cell membrane. Alternatively, it may be that DOC results in an increased rate of carcinogen transfer out of the tissue into the blood. The reason that carcinogen differs from inulin in this respect is of interest in the overall scheme of carcinogenesis and deserves further investigation.

Significantly less DMH was found in the colon mucosa of guinea pig intestine than in the mucosa of rat (table 2) despite the faster passage of DMH through the intestinal wall of guinea pig. This finding suggests that rat intestine specifically binds DMH during absorption. Rat liver also appears to bind DMH (or its ^{14}C-labeled metabolite) as indicated by more ^{14}C being present in rat liver than in guinea pig liver (table 3). Greater uptake of DMH by rat liver than by guinea pig liver would not be predicted in view of the faster absorption of DMH in guinea pigs and higher levels of DMH circulating in guinea pig blood. This finding suggests sequestering of DMH in rat liver, which correlates with metabolism of the carcinogen in this animal.

In conclusion, bile acids increase colon absorption of carcinogens through their well-documented effect of increasing intestinal permeability. An additional unexplained effect of the secondary bile acid DOC on increasing transport of carcinogen through the intestinal tissue is possible. More rapid circulation of carcinogen to the liver occurs with bile acids, and in rats conversion to the active metabolite follows. The present results appear to help explain the known effect of fecal bile acids on carcinogenesis in animals and humans. Higher levels of DMH in the liver and colon mucosa of the rat than of the guinea pig correlate with a greater rate of metabolism and binding in the rat. Although the present results show the role of bile acids on absorption of carcinogens, this role is not the only one bile acids play in carcinogenesis.

The concentration of bile acids used in the present study (10 m*M*) is higher than that normally found in the colon of humans or experimental animals. This concentration is approached, however, in the colons of certain patients (*16*) and in the study of Cohen et al. (*11*) on rats, in which it was seen that orally consumed bile acids enhance the formation of colon tumors in response to *N*-methyl-*N*-nitrosourea. In preliminary studies with the use of the protocol described above, we found that exposure of the colon mucosa to 1 m*M* DOC did not affect DMH absorption. It would be of interest to determine whether low concentrations of bile acids alter the colon properties when the exposure period is longer than the 10 minutes used in the present studies.

Liver DNA Bound In Vivo With Aflatoxin B$_1$ as a Measure of Hepatocarcinoma Initiation in Rainbow Trout[1,2,3]

Mark Whitham,[4,5] **Joseph E. Nixon,**[4,6] *and* **R. O. Sinnhuber**[4,7]

ABSTRACT—The in vivo binding of aflatoxin B$_1$ (AFB$_1$) to liver DNA was measured in rainbow trout subjected to various regimens and in coho salmon to determine if binding would correlate with tumor incidence and initiation of hepatocellular carcinoma. Establishment of timecourse binding parameters showed no significant difference between 4, 12, 24, or 48 hours. Doses of 5, 25, 100, and 300 μg AFB$_1$/kg body weight produced an almost linear increase in binding with increasing dose. Compared to that of controls, AFB$_1$–DNA binding was twofold lower in β-naphthoflavone-treated trout and twentyfold lower in coho salmon. These two comparisons reflected a decrease in the effective activation and binding of AFB$_1$, correlated with tumor incidence, and are believed to correlate with a decrease in the initiation of hepatocellular carcinoma. AFB$_1$ binding was not significantly altered by dietary protein or cyclopropenoid fatty acids, which are thought to increase hepatocellular carcinoma incidence through promotional effects. The data were consistent with the view that in vivo binding of AFB$_1$ to liver DNA is a measure of cancer initiation by AFB$_1$ and correlated with the incidence of hepatocellular carcinoma in salmonid fish.—JNCI 1981; 68:623–628.

AFB$_1$ is a potent liver carcinogen in several animal species (*1*). Mt. Shasta strain rainbow trout (*Salmo gairdneri*) are extremely sensitive to the hepatocarcinogenic effects of AFB$_1$ and provide an excellent animal model for the study of this mycotoxin (*2*).

Biologic activation is required for the conversion of AFB$_1$ to metabolites that will bind nucleic acid (*3, 4*), reduce bacterial viability (*5–7*), cause mutagenesis (*8, 9*), and undergo detoxification to the 2,3-dihydro-2,3-dihydroxy-AFB$_1$ (*10*). In vivo macromolecular covalent binding of AFB$_1$ occurs to a much greater extent with nucleic acids than with protein (*11–13*) and has been suggested to be a better indicator of cancer initiation than binding to protein (*12*). Further evidence for the importance of nucleic acid binding is that phenobarbital treatment of rats decreases the incidence of AFB$_1$-induced hepatocarcinogenesis and decreases in vivo AFB$_1$ binding to DNA, while protein binding is unaffected (*12, 14*). Considerable indirect evidence has implicated AFB$_1$-2,3-oxide as the reactive species binding DNA and the nucleophilic N^7 position of guanine as the major site of attack (*9, 15–18*).

Many factors can significantly alter AFB$_1$-induced toxic and carcinogenic effects. Both the level and source of dietary protein affect hepatoma development in rats (*19, 20*) and rainbow trout (*21, 22*). The in vivo binding of AFB$_1$ to chromatin and DNA in low-protein-fed rats was lower than that in controls fed adequate protein (*23*). CPFA, naturally present in the seed oils of plants such as cotton and kapok, also markedly alter AFB$_1$-induced hepatocarcinogenesis (*24*). CPFA are carcinogenic when fed alone to trout (*24*) and act as powerful synergists that increase tumor incidence and growth when they are incorporated into rainbow trout diets with AFB$_1$ (*25–28*), aflatoxin M$_1$ (*29*), and aflatoxin Q$_1$ (*30*). In addition, CPFA alter lipid metabolism and produce extensive cell damage (*31, 32*). Drastic differences in the hepatocellular carcinoma incidence resulting from AFB$_1$ treatment occur in different species. The magnitude of AFB$_1$–nucleic acid binding in the rat, hamster, and mouse correlates well with the relative susceptibility of each species to AFB$_1$-induced hepatocarcinogenesis (*11, 13*).

Covalent binding to macromolecules in combination with toxicity studies provides a means for determining the formation and involvement of reactive metabolites in toxic responses such as cancer (*33*). For the assessment of relationships between the covalent binding of reactive metabolites to macromolecules and toxicities, the covalent binding should be determined when it is maximal (*33*). Alteration of cellular DNA is currently viewed by many investigators as the most attractive mechanism for initiation of carcinogenic processes by chemicals (*34*). In the case of AFB$_1$, the quantity of AFB$_1$–DNA adducts has been suggested as a measure of the activation of AFB$_1$ (*3, 4*) and possibly as an indication of the initiation of cancer (*12, 34*).

The purpose of this investigation was to determine whether in vivo binding of AFB$_1$ to salmonid liver DNA has application for prediction of tumor initiation. The relative binding was measured under specific protocols where initiation or promotional factors are thought to affect the tumor incidence. The following parameters were evaluated: *a*) the influence of source and level of dietary protein on AFB$_1$ binding in trout, *b*) the impact of CPFA on AFB$_1$ binding in trout, *c*) the comparison of AFB$_1$ binding in trout with

MATERIALS AND METHODS

[^3H(G)]AFB_1 (0.35–0.45 μCi/μg) was administered by ip injection at 50 μg AFB_1/kg body weight in 0.05–0.25 ml of 95% ethanol except where stated otherwise. We made injection solutions by mixing unlabeled AFB_1 (grade A; Calbiochem-Behring Corp., San Diego, Calif.) with [^3H(G)]-AFB_1 (15 Ci/mmol; Moravek Biochemicals, Brea, Calif.). [^3H(G)]AFB_1 was 98% radiochemically pure as determined by radiochromatography. Chemical purity of each AFB_1 shipment was confirmed by UV scanning and by thin-layer chromatography.

Animals and diets.—Mt. Shasta strain rainbow trout (*S. gairdneri*) eggs from our brood stock and coho salmon (*O. kisutch*) eggs obtained locally were hatched and reared at the Food Toxicology and Nutrition Laboratory, Oregon State University. Rainbow trout were fed Oregon Test Diet (*2*) in all experiments until the dietary changes indicated below were initiated or until AFB_1 treatment. Coho salmon in experiment 4 were fed Oregon Moist Pellet (*35*) until treatment with AFB_1.

Experiment 1 was conducted to follow the time-course binding in rainbow trout. Trout 10 months old and weighing approximately 45 g each were treated with AFB_1 (83 μg/kg body wt), fasted for 4, 12, 24, or 48 hours, and then killed. In experiment 2, the effect of AFB_1 dosage on total DNA binding was determined. Trout 11 months of age and weighing approximately 53 g each were administered AFB_1 at 5, 25, 100, or 300 μg/kg body weight, fasted for 24 hours, and then killed. Experiment 3 was done to determine the influence of both source and level of dietary protein on AFB_1 binding. Groups of trout 6 months old were fed 40, 50, 60, or 70% semipurified protein diets from two different protein sources, FPC or casein (table 1). After 5 months on these diets, trout weighing 58–71 g were treated with AFB_1, fasted for 24 hours, and then killed. In experiment 4, trout and coho salmon 13 months of age and weighing approximately 74 and 61 g, respectively, were studied to compare the DNA binding in different salmonid species. Both groups of fish were individually weighed and treated with AFB_1, fasted for 24 hours, and then killed. The influence of CPFA on AFB_1–DNA adduct formation was determined in experiment 5. Trout 14 months of age remaining from experiment 3 and weighing 95–145 g were used. These fish were fed 40 or 70% casein or FPC diet (table 1) for 7 months and were divided equally into two tanks for each diet. CPFA were incorporated into the diet at 100 ppm with the salmon oil in 1 group from each protein diet and fed from 23 to 32 days before AFB_1 treatment. The group not treated with CPFA represented the control. Each CPFA-fed group and its respective control were simultaneously administered AFB_1, fasted for 24 hours, and then killed. In experiment 6, the influence of β-naphthoflavone on AFB_1 binding was studied in 2 groups of trout 14 months of age and weighing 80–125 g. Trout were individually weighed and given ip injections of either β-naphthoflavone (Aldrich Chemical Co., Milwaukee, Wis.) at 100 mg/kg body weight in 0.27–0.43 ml of corn oil or with 0.3 ml of corn oil. Both groups were fasted exactly 4 days, treated with AFB_1, and then killed 24 hours later.

Extraction and purification of DNA.—Except for experiment 1, all fish were killed by a cranial blow 24 hours after injection with AFB_1. Livers were excised and immediately perfused with 0.9% NaCl and then nuclei were isolated according to the method of Hymer and Kuff (*36*). DNA was extracted from the final nuclear preparation and purified as described by Marmur (*37*) and modified by Croy and Wogan (*38*). The sequence of steps was extraction, precipitation, treatment with RNase, treatment with pronase, and precipitation. The purified DNA was hydrolyzed in 0.5 *N* perchloric acid at 80°C for 15 minutes (*11*).

Quantitative determinations.—Liver [^3H(G)]AFB_1 levels were determined by solubilization of 0.2-ml aliquots from whole-liver homogenates in 1 ml Soluene 350 (Packard Instrument Co., La Grange, Ill.) and counting in 10 ml Dimilume-30 (Packard Instrument Co.). Radioactivity of DNA hydrolysates was obtained by counting aliquots in Aquasol (New England Nuclear Corp., Boston, Mass.). Radioactivity was measured in a Beckman LS 7500 scintillation counter. A measure of covalent binding, AFB_1–DNA adduct formation, was calculated by the conversion of the radioactivity in the DNA hydrolysate to picomoles of AFB_1 and expressed as picomoles AFB_1 per milligram DNA. Variability of the DNA isolation and purification technique was analyzed by the measurement of the binding of three separate aliquots from the same whole-liver homogenate.

DNA hydrolysates were quantitated by the diphenylamine reaction (*39*), RNA contamination by the orcinol reaction (*40*), and protein contamination by the Lowry-Folin procedure (*41*). AFB$_1$ solutions were quantitated in 95% ethanol with the use of a molar extinction coefficient of E (362 nm)=21,800/cm. All colorimetric reactions and UV absorbance readings were determined in a Beckman Acta CIII spectrophotometer.

RESULTS

Effect of time and dose on binding of AFB$_1$ to trout liver DNA.—Covalent binding was maximal at 24 hours after AFB$_1$ administration; however, no significant difference was found between any of the sampling times over the period of 4–48 hours (table 2). An approximately linear increase in binding was obtained with increasing dose levels with a high correlation coefficient of binding for doses over the range 5–300 µg AFB$_1$/kg body weight (table 3).

Dietary protein effects on AFB$_1$ binding.—Binding of AFB$_1$ to trout liver DNA was significantly greater in fish fed 70% casein than in fish fed 70% FPC (table 4). However, binding in the fish fed 40, 50, and 60% casein was not significantly different from that in each corresponding group fed FPC. The 60% protein level from each source produced the greatest binding, but no significant differences were found between casein levels. The binding in the group fed 60% FPC was significantly greater than that in the groups fed either 50 or 70% FPC.

CPFA effect on AFB$_1$ binding to rainbow trout DNA.—Total AFB$_1$ in liver after 24 hours in trout maintained on 40 and 70% casein or FPC and fed 100 ppm CPFA for 23–32 days was not significantly different from that in controls not fed CPFA (table 5). AFB$_1$ binding to liver DNA in the CPFA-fed trout was not significantly different from that in controls either. Total liver AFB$_1$ tended to be higher and AFB$_1$ in DNA tended to be lower in the CPFA-fed trout.

Trout	243.0±85.9
Coho salmon	10.6±01.0

[a] At least 5 livers were pooled for each sample; n=3. Values are means ± SD. Values are significantly different; P<0.05 (Student's t-test).

Calculations were also performed from this study on the amount of AFB$_1$ present in liver tissue at 24 hours from 24 samples relative to the administered dose. Of the total administered [^{3}H(G)]AFB$_1$ dose, 15.4% (range: 10.7–21.5) was present in the liver and 3.1% (range: 2.3–5.0) was covalently bound to DNA. Approximately 20.4% (range: 15.0–25.3) of the total [^{3}H(G)]AFB$_1$ in the liver was bound to DNA.

AFB$_1$ binding to liver DNA in coho salmon and β-naphthoflavone-treated trout.—Table 6 shows the relative binding of AFB$_1$ to liver DNA in trout and coho salmon. Binding in coho salmon, which are less sensitive to AFB$_1$ carcinogenesis than trout, was approximately twentyfold lower than that in the trout. Table 7 shows the effect of pretreatment with 100 mg β-naphthoflavone/kg body weight 4 days before AFB$_1$ injection on [^{3}H(G)]AFB$_1$ binding in trout liver. Total label from [^{3}H(G)]AFB$_1$ in the liver was reduced twofold by β-

naphthoflavone, and binding to DNA was significantly reduced to 60% of that of the untreated controls. Variability of binding as a result of isolation procedures was determined in this experiment and calculated to be 1.2%.

DISCUSSION

Time-course and dose-response data are of critical importance for the determination of optimum conditions in binding studies and were obtained as essential information for use in subsequent experiments with rainbow trout. The measured binding of AFB$_1$ to rainbow trout liver DNA over the 48-hour period monitored was not significantly different (table 2). This observation is in marked contrast to that in the rat in which the maximum binding was from 2 to 6 hours followed by a rapid removal of bound AFB$_1$ between 6 and 24 hours (*11*). Two possible explanations for the difference are: *a*) Most of the binding occurs earlier than 4 hours after AFB$_1$ treatment and removal of adducts is extremely slow and *b*) excision repair or removal of bound AFB$_1$ occurs at a rate approximately equal to that of covalent binding to DNA, possibly due to slower absorption and metabolism of injected AFB$_1$ in trout at 10°C compared to rats at 37°C. If persistence of total DNA binding is an indicator of cancer initiation, the longer effective exposure time of rainbow trout, regardless of mechanism, would appear to place them at greater risk to the hepatocarcinogenic activity of AFB$_1$ than rats and could explain the extreme sensitivity of rainbow trout to the hepatocarcinogenic effects of AFB$_1$. From this experiment, a 24-hour sampling time was used in subsequent work to compare the effect of various parameters on binding. The approximately linear dose-binding data shown in table 3 indicate that binding sites for AFB$_1$ were not saturated in the dose range employed. The slightly upward trend of this curve could possibly indicate an inductive effect on the MFO system caused by increasing dosage, with greater activation and subsequent binding, or might indicate proportionally less loss of activated AFB$_1$ to detoxification reactions and binding to protein and RNA at higher doses.

Dietary protein of varied source and level has recently been observed to alter AFB$_1$-induced hepatocarcinogenesis in rainbow trout (*21, 22*). Increasing dietary protein in these studies increased AFB$_1$ tumor induction with both casein and FPC as a protein source. In addition, trout exposed to AFB$_1$ as embryos were observed to have a greater hepatoma incidence with increasing dietary protein levels (*22*); in that experiment, hepatomas were initiated in the embryos, so variable dietary protein in the growing trout affected tumor formation by altering promotional rather than initiating factors. These results are consistent with, and supported by, the lack of effect of variable dietary protein on AFB$_1$ binding in our study. Factors that influence only the promotional stages of tumor development should not influence the extent of initiation by chemical carcinogens (e.g., AFB$_1$ binding to critical sites on DNA). The significance of the differences in AFB$_1$ binding observed between 70% casein and 70% FPC treatments and between 60% FPC and 50 and 70% FPC treatments is not clear because the differences neither occurred in any pattern nor correlated with tumor incidence.

CPFA are far less carcinogenic than is AFB$_1$ in trout, but when fed in conjunction with AFB$_1$ (*25–28*) or fed to trout treated with AFB$_1$ as embryos (*42*), CPFA are potent synergists that greatly enhance tumor incidence and growth. In light of these biologic effects, CPFA may be classified primarily as tumor-promoting agents in the trout hepatocarcinoma model. Thus CPFA, as well as dietary protein, would not be expected to significantly increase initiating events. In fact, a slight reduction in AFB$_1$ binding to DNA with CPFA feeding was noted in this study and is in agreement with reduced AFB$_1$–DNA adduct formation by chronic CPFA treatment previously observed at this laboratory (Nixon JE: Unpublished data). In addition, recent studies (Taylor MJ, Bailey GS, Selivonchick DP: Unpublished data) showed that AFB$_1$ binding to DNA in intact isolated hepatocytes from CPFA-fed trout was reduced compared to that in controls. CPFA alteration of membrane structure may be responsible for reduced microsomal cytochrome P$_{450}$ and protein content and reduced MFO activity reported in CPFA-fed trout (*43–45*). Therefore, reduced microsomal activation presents an explanation for the slightly decreased in vivo AFB$_1$–DNA binding noted in this study. But while initial alkylation may be slightly decreased by dietary CPFA, promotion of these lesions by CPFA leads to a greatly elevated tumor response. At present, we have no explanation for the mild carcinogenic activity of CPFA when fed alone.

Rainbow trout exposed to AFB$_1$ as embryos are much more sensitive to hepatocarcinogenesis than coho salmon administered the identical embryo exposure and dietary regimen (Hendricks JD, Sinnhuber RO: Unpublished data). This observation suggests that differences in tumor-initiating events and not promotional factors may be responsible for the difference in hepatoma development in these two species. The twentyfold higher binding of AFB$_1$ in rainbow trout relative to the AFB$_1$ binding in coho salmon noted in this study (table 6) supports the hypothesis that binding can predict tumor initiation and incidence. However, conditions used in this study were those previously established for rainbow trout. Since relative to rainbow trout salmon grow poorly in captivity, data on time-course binding and on liver uptake and removal of AFB$_1$ in coho salmon would aid our understanding of the significance of this difference. However, in studies done to date (Loveland PM, Nixon JE, Hendricks JD, Sinnhuber RO: Unpublished data) in vitro metabolism of AFB$_1$ and MFO activities are generally lower in coho salmon than in trout. Faster DNA repair in coho than in trout would have explained the lower amount of AFB$_1$–DNA in coho than in trout, but we have no reason to believe that occurs.

Phenobarbital, an inducer of rat liver MFO activity, decreases in vivo AFB$_1$–nucleic acid binding and AFB$_1$-induced hepatocarcinogenesis in rats (*12, 14, 46*). Another MFO inducer, β-naphthoflavone, has been observed to dramatically increase MFO activity in rainbow trout (*47, 48*) and has been shown to provide tumor protection in some animal species (*49*). Recently, in our laboratory β-naphthoflavone was shown to protect against AFB$_1$-induced hepatocellular carcinoma (Hendricks JD, Nixon JE, Bailey GS, Sinnhuber RO: Unpublished data). Treatment with β-naphthoflavone, which is an MCA-type inducer (*47*), apparently increases overall AFB$_1$ metabolism, and detoxification reactions predominate over initiation events and result in tumor reduction (*49*). This observation is supported by the work of Gurtoo and Dahms (*50*) who have reported that several MFO enzymes are involved in AFB$_1$ metabolism and the enzymes react differently to MFO inducers and inhibitors. In vitro metabolism of AFB$_1$ to less toxic AFM$_1$ was stimulated while activation to AFB$_1$-2,3-oxide was inhibited by pretreatment of rats and mice with MCA. Thus if β-naphthoflavone reduces tumor incidence by decreasing initiation events in the trout system and AFB$_1$–DNA binding is an indicator of initiation., β-naphthoflavone should reduce AFB$_1$ binding. This view is supported by the fact that β-naphthoflavone treatment compared to treatment for controls did reduce AFB$_1$ binding by 40% in this study. In addition, the simultaneous twofold reduction in liver AFB$_1$ levels suggests that such treatment increased detoxification activity and enhanced conversion of AFB$_1$ to readily excretable metabolites. This view was further supported by recent work in our laboratory (Bailey GS, Taylor MJ, Selivonchick DP: Unpublished data) which showed that intact isolated hepatocytes from β-naphthoflavone-fed trout metabolized more AFB$_1$ and formed twentyfold more AFM$_1$, slightly more water-soluble metabolites, 70% less aflatoxicol, and 30–50% less AFB$_1$–DNA adducts than did hepatocytes from controls.

AFB$_1$–DNA adduct formation in the trout system under the conditions described in this paper seems to correlate well with the expected relative levels of binding, where promotional or initiating effects are the determining influence. When tumor development is attributed to promotional factors, such as dietary protein and CPFA, no relationship with DNA binding would be expected, and none was observed in this study. However, when the quantity of initiating events is presumed altered by a drug (β-naphthoflavone) or by species differences (coho salmon vs. trout), a positive relationship with DNA binding was expected and observed. Thus the data are consistent with the view that in vivo AFB$_1$–DNA binding is a measure of initiation of cancer by AFB$_1$ and correlates with the incidence of hepatocellular carcinoma in rainbow trout when promotional effects are not involved. Initiation as used in this discussion is the sum of activities involving AFB$_1$ that results in AFB$_1$–DNA adducts after 24 hours. The quantity of AFB$_1$ that was activated to AFB$_1$–2,3-oxide, that survived competing reactions to bind covalently to DNA, and that survived DNA repair to persist for 24 hours was used as a measure of initiation. That measure of initiation correlated well with carcinoma incidence. We realize that initiation is a complex process and mutagenic and carcinogenic activities correlate better with persistence of specific adducts than with total alkylation of DNA (*51*). However, total AFB$_1$–DNA adducts appear to be adequate for estimating initiation under in vivo conditions in the trout system and may be a useful assay for predicting tumor incidence.

AFB$_1$–DNA adducts in the trout system have been analyzed and were found to be remarkably similar to AFB$_1$–DNA adducts from rats (*52*). We are presently studying AFB$_1$–DNA adduct profiles in trout and salmon subjected to different nutritional, inducer, and inhibitor regimens to determine correlation of adduct profile and tumor incidence. Further study with coho salmon, a salmonid species resistant to AFB$_1$-induced hepatocarcinogenesis, and with MFO inducers such as β-naphthoflavone, which apparently alter initiation and detoxification pathways, could provide important information in understanding mechanisms of chemical carcinogenesis.

B16 Melanoma Cell Variants: Irreversible Inhibition of Growth and Induction of Morphologic Differentiation by Anthracycline Antibiotics[1,2,3]

Avraham Raz[4,5]

ABSTRACT—The interaction of doxorubicin and *N*-trifluoroacetyladriamycin-14-valerate (AD32) with B16 melanoma cell variants that exhibit distinct metastatic properties was explored. The addition of the two drugs to cell monolayers at noncytolytic concentrations for 16 hours resulted in irreversible inhibition of proliferation of tumor cells and loss of their tumorigenicity after injection into inbred C57BL/6 mice. Cessation of melanoma cell proliferation was accompanied by cellular and nuclear hypertrophy and the development of axon-like processes. As assessed by drug-specific cytofluorescence, after 16-hour exposure of the cells to doxorubicin and AD32, the drugs were localized in the nuclei. Incubation of drug-treated cell monolayers for 6 additional days in drug-free culture medium led to the complete disappearance of nuclear stain. The highly metastatic B16-F10-B2 cell line was the most sensitive to the drugs' effects, whereas the other two malignant melanoma cell lines, although differing in their metastatic capabilities, exhibited similar sensitivities to the drugs' effects. Doxorubicin was notably more potent than AD32 in its growth inhibitory effect on the three tested melanoma cell variants. The possible mutagenic effect of anthracycline drugs on tumor cells was discussed.—JNCI 1982; 68:629–638.

Metastasis, the spread of neoplastic disease, is responsible for most therapeutic failures in clinical oncology. The metastatic process involves linked sequential steps in which neoplastic cells are detached from the primary tumor and disseminate to distant organs where they are arrested and divide to form new tumor foci. Despite the development of complex and aggressive therapeutic regimens, most deaths in cancer patients are due to the survival and growth of unique metastatic cells that are nonresponsive to the treatment [for reviews *see* (*1–3*)]. In the determination of the therapeutic schedule, the veracity of results from experimental tumor systems depends on the use of an appropriate biologic model (*4*). There would appear, then, to be a need for information on the susceptibility of tumor cell variants that exhibit distinct metastatic properties to anticancer drugs. The best characterized tumor system with regard to cellular properties and metastasis is the B16-F malignant melanoma series (*5*). It was shown that the parental B16 melanoma tumor is populated with cells that exhibit high and low metastatic potential as well as preferential metastasis to a particular organ (*5–8*).

Anthracycline antibiotics exhibit antineoplastic activity in experimental tumors (*9–12*) as well as in human malignant diseases (*13–15*). The doxorubicin and daunorubicin derivatives have been shown to intercalate with DNA, both via hydrophobic interactions between base pairs of the DNA and the glycon and by binding of the amino group of the sugar residues in the drug to the phosphate moiety of DNA (*16–18*). The development of different analogs like AD32, which exhibits a superior therapeutic activity in comparison to that of the two former molecules (*19*) but does not bind to calf thymus DNA (*20*) and does not exhibit drug-specific nuclear fluorescences in WI-38 fibroblasts (*21*), has promoted the idea that AD32 is metabolized to a nonfluorescence DNA-binding metabolite (*21, 22*).

In the present study we report that exposure of three B16 melanoma cell variants of different metastatic potential to doxorubicin and AD32 results in the irreversible inhibition of cell proliferation and is accompanied by a dramatic alteration in cell morphology.

MATERIALS AND METHODS

Anthracycline drugs.—Doxorubicin and AD32 were supplied by Dr. A. Mantovani (Istituto di Ricerche Farmacologiche Mario Negri, Milan, Italy).

Tumor cell variants.—The B16-F1 cell line (low incidence of lung colonization) was derived from pulmonary metastases produced by iv injection of B16 melanoma cells (*4*). The B16-F10 cell line (high incidence of lung colonization) was selected by successive passage of tumor colonies for ten in vivo–in vitro selections, as described previously (*4*). These 2 cell lines were supplied by Dr. I. J. Fidler (NCI-Frederick Cancer Research Facility, Frederick, Md.). The B16-F10-B2 (exhibiting preferential growth in the brain) is a variant cell line selected from the B16-F10 cell line after two in vivo–in vitro selection cycles of brain tumors, as described in detail previously (*7*).

Cell cultures.—All cultures were maintained on plastic plates in Dulbecco's modified Eagle's minimum essential medium supplemented with nonessential amino acids, L-glutamine, vitamins, antibiotics (Grand Island Biological

[5] I thank Professor M. Feldman for his interest during this work, Dr. R. Lotan and Dr. A. Ben-Zeev for their careful review of the manuscript, Mrs. M. Baer for her handling of the manuscript, and Mrs. R. Karkash for her excellent technical assistance.

Co., Grand Island, N.Y.), and 10% fetal bovine serum (Bio-Lab, Jerusalem, Israel) (cEMEM). Cell cultures were grown at 37°C in a humidified atmosphere containing 7% CO_2. To ensure reproducibility, we did all experiments with cultures from frozen stocks. For passage and enumeration, we harvested the tumor cells from cultures by overlaying the cells with a thin layer of 0.25% trypsin for 2 minutes. Cell counting was performed with the use of an electronic particle counter (Coulter counter, model ZBI; Coulter Electronics Inc., Hialeah, Fla.). Cell viability was assessed by trypan blue exclusion, and only suspensions with single cell viability above 95% were used in these studies.

Growth inhibition assay.—Cells were plated at 10^4 cells/dish (35 mm in diameter) in 1.5 ml cEMEM. After a phase of cell adherence (2–4 hr at 37°C), the anthracycline drugs were added; at various intervals the cultures were rinsed two times with PBS (pH 7.2), and fresh cEMEM was added to the cultures. The cells were detached and counted on day 7. The percentage of growth inhibition by each drug concentration was calculated from the 100% of drug-free control cultures. The experiments were preformed at least three times in triplicates.

Morphologic observations and intracellular distribution of anthracycline drugs.—Tumor cells (10^3) were plated in Lab-Tek tissue culture chamber slides (Lab-Tek Products, Naperville, Ill.) (phase microscopy) or on 25-mm-diameter cover slips that were placed in tissue culture dishes (fluorescence microscopy). Cell monolayers were fixed with 3% paraformaldehyde in PBS (pH 7.2) (60 min, 23°C). Before being washed three times with PBS, the cells were mounted in 90% glycerol in PBS, examined, and photographed with a Karl Zeiss microscope. Photomicrographs were taken on Kodak films (Plus-X, 32 ASA; Tri-X, 400 ASA).

RESULTS

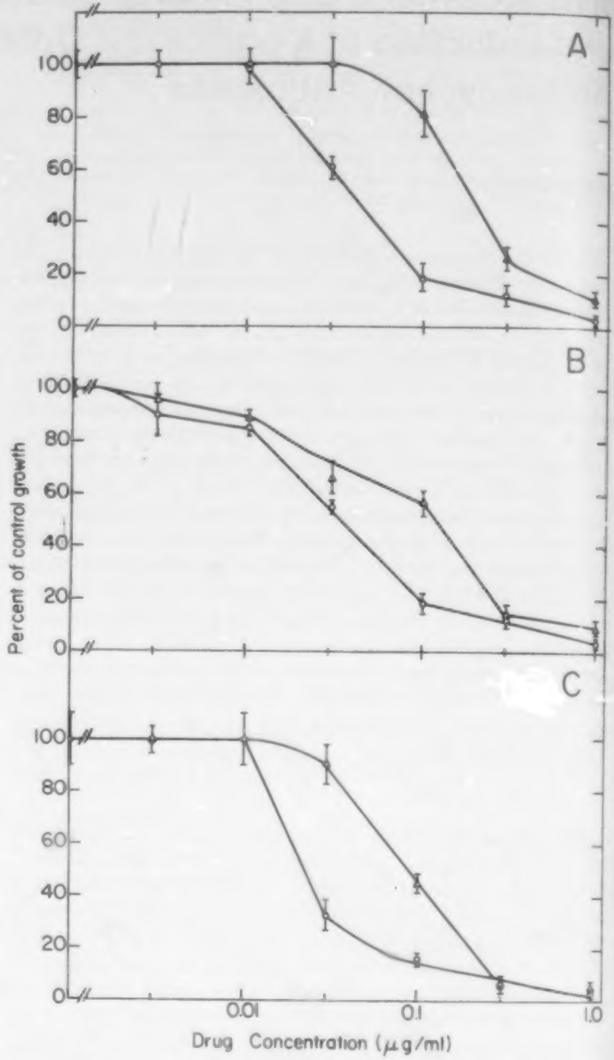
Growth Inhibitory Effect of Doxorubicin and AD32 on B16 Melanoma Cell Variants

The melanoma cell variants B16-F1, B16-F10, and B16-F10-B2 were seeded (10^4 cells/plate) in cEMEM; 4 hours later, doxorubicin and AD32 were added at final concentrations ranging from 0.003 to 1.0 μg/ml. The cells were incubated with the drugs for 16 hours at 37°C, washed, and reincubated for 6 days in drug-free cEMEM. The relative sensitivities of the 3 tumor cell lines to the anthracycline drugs are presented in text-figure 1. The growth inhibition by doxorubicin and AD32 was concentration-dependent, and doxorubicin was notably more potent than AD32 in its effect on tumor cell growth (text-fig. 1).

Exposure of the 3 tumor cell lines for 16 hours to 1 μg/ml of either doxorubicin or AD32 markedly inhibited cell proliferation (85–95%). Cell viabilities at the end of the incubation were similar to those found in drug-free cultures. Furthermore, the number of cells in the complete growth-inhibited cultures was similar to the number of cells that were plated. These results suggest that the drug treatments were not lytic and that the observed growth inhibitory effects were probably due to an irreversible inhibition of tumor cell proliferation.

The concentration ratios of AD32 to doxorubicin required for 50% growth inhibition of B16-F1, B16-F10, and B16-F10-B2 were 4.8, 3.1, and 3.9, respectively, demonstrating the superior potency of doxorubicin to inhibit cell growth. The B16-F1 and B16-F10 exhibited similar sensitivity to the growth inhibition effect of the drugs, whereas the B16-F10-B2 cells were about 1.5–2 times more sensitive to the two antibiotic drugs as were the B16-F1 and B16-F10 melanoma cell lines.

The drug-treated B16-F1 melanoma cells could not escape from the arrest in cell division through weekly subculturing for a month; eventually, the cells produced intracellular vacuoles and died. Implantation sc of treated cells in syn-



TEXT-FIGURE 1.—Effect of doxorubicin (○—○) and AD32 (△—△) on growth of B16-F1 (A), B16-F10 (B), and B16-F10-B2 (C). Cells were incubated with the various drug concentrations for 16 hr at 37°C, washed, and reincubated in drug-free cEMEM for 6 additional days. Cells were detached with 0.25% trypsin, and cell number was determined with a Coulter counter. *Each point* represents mean ± standard deviation calculated from triplicate experiments.

geneic C57BL/6 female mice (5×10^4 cells/mouse) failed to produce any detectable tumors after 3 months, whereas the control C57BL/6 female animals died within 30–35 days (10 mice/group).

Morphologic Changes of B16-F1 Melanoma Cells Induced by Doxorubicin and AD32

When B16-F1 melanoma cells were incubated for 16 hours with 0.1 μg doxorubicin/ml and 0.3 μg AD32/ml, most of the adherent cells lost their characteristic bipolar appearance (fig. 1A) and displayed exaggerated "dendrite"-like formation and an increase in size (figs. 1A, 1B). Further incubation of the 16-hour drug-treated monolayers in fresh cEMEM for 6 days led to dramatic morphologic alterations (figs. 2A–2E). The cells in the untreated cultures continued to proliferate normally and developed into large tumor cell colonies (fig. 2A); the melanoma cells in the drug-treated monolayers exhibited marked hypertrophy (figs. 2A, 2B). The cells were flattened extensively and full of filamentous elements; under these conditions cells occupied a substrate that was normally covered by 50–100 control cells (cf. fig. 2A with figs. 2B and 2C). In some cells binucleation could be observed (fig. 2B), suggesting that the cells can pass through one nuclear division with an impairment in cytokinesis. A completely different and striking morphologic alteration that the cells undergo in response to the drug treatment is presented in figures 3A and 3B. The cells developed enormously large axon-like processes that could exceed 250 μm in length (figs. 3A, 3B). Whether the cells extended these processes from the main cellular body or whether they migrated on the substrate leaving cytoplasmic tracks is still an open question.

Cytofluorescence Localization of Doxorubicin and AD32

One possible explanation for the mode by which the anthracycline antibiotics irreversibly inhibit melanoma cell proliferation is that the drugs bind and remain constantly within intracellular compartments, thus inducing permanent effects. To examine this possibility, we processed B16-F1 cells grown on glass cover slips for fluorescence visualization. Representative fluorescence and interference (Nomarski) photomicrographs of cells incubated for 16 hours with the drugs are shown in figs. 4A–4D. The cells were seeded at high densities so that a maximum number of cells could be photographed in one microscope field. Cells incubated with doxorubicin (figs. 4A, 4B) and AD32 (figs. 4C, 4D) exhibited the same basic pattern of cytofluorescence and nuclear localization. All the cells apparent to the Nomarski optics were fluorescent, indicating that all cells in the monolayer probably have an equal chance to be affected by the added drugs. After 6 days of incubation in drug-free cEMEM, no nuclear fluorescence could be detected in both doxorubicin- and AD32-treated cultures (figs. 5A, 5B), suggesting either that the drugs were metabolized to nonfluorescent derivative(s) or that they were extruded from the cells. Aside from the different concentrations of doxorubicin and AD32 needed to block melanoma cell proliferation, the drugs affected nuclear shape differently (*see* figs. 2A–2C, 5A–5D). Whereas the nuclei of doxorubicin-treated cells (fig. 2B; fig. 5A) were enlarged but remained spherical, the nuclei of AD32-treated cells underwent an enlargement that was accompanied by irregularity and development of lobes.

DISCUSSION

The two anthracycline antibiotics doxorubicin and AD32 irreversibly inhibited in a time- and dose-dependent manner the proliferation of B16 melanoma cells. Doxorubicin was notably more potent than AD32 in its growth inhibition effect on the three tested cell variants. The present study demonstrates in vitro heterogeneity in drug response among in vivo selected cell lines that exhibit distinct metastatic properties. Although the most metastatic B16 melanoma cell line B16-F10-B2 (*7*) was the most sensitive to the drug effect, one cannot conclude that susceptibility to the drugs correlates with the metastatic properties, since the other melanoma cell lines B16-F1 and B16-F10, while demonstrating marked differences in their metastatic behavior (*5, 32*), required similar drug concentrations to achieve 50% growth inhibition. Therefore, metastatic heterogeneity of tumor cells does not necessitate similar heterogeneity of other biologic parameters, i.e., susceptibility to cytotoxic drugs. Lotan and Nicolson (*24*) arrived at a similar conclusion when they found that various clones and cell lines of B16 melanoma are heterogeneous in the susceptibility to growth inhibition exerted by retinoic acid. Notwithstanding these biologic complexities, our study produced results that may contribute to the understanding of the mode of action of anticancer drugs on malignant cell variants selected from the same parental tumor.

The exact mechanism by which doxorubicin and AD32 irreversibly block cellular division of B16-F melanoma variants is not clear, and both drugs seem to exert their effect via similar mechanisms. Cells that were exposed for 16 hours to doxorubicin and AD32 exhibited marked nuclear fluorescence, which was abolished after washing and further incubation for 6 days in cEMEM. It is, however, possible that the permanent effect of the drugs is due to either a continuous presence of nonfluorescent metabolite(s), to the drugs being extruded after the cells were mutated to nondividers, or both. Indeed, anthracycline antibiotics were found to be mutagens in the Salmonella test (*25, 26*), to be able to transform cells in culture (*27*), and to induce tumors in rats (*27, 28*). Furthermore, an irreversible G_2 arrest of 70–90% of human lymphoma cells treated with doxorubicin was observed over a 72-hour period after drug removal (*29*).

The nuclear fluorescence observed in AD32-treated melanoma cells is in contrast to our previous report, where AD32-treated murine peritoneal macrophages showed mainly cytoplasmic fluorescence (*30*) as reported for WI-38 fibroblasts (*21*). Conceivably, the observed difference is due to the differences in cell types or to the capability of B16 melanoma cells to produce a fluorescent metabolite(s) from AD32 that has high affinity to the DNA. In a recent report, however, it was demonstrated that there is no clear correlation between cytofluorescence localization of a drug and its accumulation by intact L1210 cells or isolated nuclei (*31*).

The cessation of B16 melanoma cell proliferation is associated with a dramatic alteration in cell morphology. First, the cells lose their bipolar appearance, show exaggerated dendrite formation, and increase in size. Later, they followed two morphologic pathways: *a*) enormous increase in size (over fiftyfold to a hundredfold) and *b*) development of large axon-like processes possibly exceeding 250 μm. Cellular hypertrophy is a common consequence of treatment with agents inhibiting DNA synthesis (*32*). The observed morphologic changes reported here were regarded in neuroblastoma cells as evidence of cellular differentiation (*33, 34*) and in virus-transformed fibroblasts as acquisition of morphologic characteristics of nontransformed fibroblasts (*35*).

A wide variety of melanoma cells from diverse origins responded in vitro to changes in the intracellular levels of cyclic nucleotides by "morphologic differentiation." Melanocyte-stimulating hormone and cAMP caused Cloudman S91 melanoma cells to become flattened and more dendritic (*36*); the KHm-1 human melanoma cells altered their morphology in response to cAMP, to theophylline, or to incubation in serum-free medium (*37*). Cholera toxin and cAMP promote the formation and elongation of processes of Greene hamster melanoma cells (*38*). B16 melanoma cells treated with cAMP, phosphodiesterase inhibitors, and GTP responded in cessation of cell proliferation and altered morphology characteristic of the differentiated state (*39–41*). Thus melanoma cells are susceptible to morphologic differentiation in vitro; but whereas most of the above treatments induced reversible effects, the treatment of B16 melanoma cells with doxorubicin and AD32 induced irreversible cessation of cell proliferation and alteration of both cellular and nuclear morphology. Recently, doxorubicin was found to have significant therapeutic activity against various human melanoma xenografts in athymic mice (*42*).

On the basis of our results, B16 melanoma cells seem to be a highly suitable model system for the study of the mode of action of anthracycline antibiotics on neoplastic cells. Thus attempts to identify the molecular events accompanying the interaction of doxorubicin and AD32 with B16 melanoma are ongoing in our laboratory.

Differing Stem Cell Self-Renewal of Lectin-Separated Murine Bone Marrow Fractions[1,2,3]

Andrew L. Salner,[4] **Jane E. Obbagy,**[4] *and* **Samuel Hellman**[4]

ABSTRACT—The success of bone marrow transplantation depends not only on the engraftment of adequate numbers of hematopoietic stem cells but also on their self-renewal capacity, which must be sufficient to provide lifetime hematopoiesis. The lectin peanut agglutinin (PNA), when exposed to bone marrow, causes separation into two distinct fractions. The agglutinated fraction not only is enriched with colony-forming units—spleen but also is devoid of graft-versus-host (GVH) activity when injected into allogeneic lethally irradiated recipients, and therefore, it is considered to be an ideal source for bone marrow transplantation. The absence of GVH activity is presumably due to the separation of mature thymocytes into the nonagglutinated fraction and functionally immature thymocytes into the agglutinated fraction. Although there has been speculation that immature hematopoietic stem cells also selectively bind to PNA, other evidence suggests that the relationship of lectin binding specificity to level of maturity varies in different tissues. This study was performed to assess the self-renewal capacity of lectin-separated bone marrow stem cells. Results indicate that the self-renewal of the agglutinated fraction is significantly lower than that of the unfractionated bone marrow; such self-renewal of the nonagglutinated fraction is higher. This is further evidence for the heterogeneity of the stem cell pool. Stem cell enrichment should not be the goal in bone marrow transplantation; rather, the goal should be utilization of stem cells with the greatest self-renewal potential.—JNCI 1982; 68:639–641.

The stem cell compartment consists of a continuum of cells, with varying capacity for self-renewal and reciprocal likelihood for differentiation (*1, 2*). Under normal circumstances, the proliferative capacity of the bone marrow stem cell is not a limiting factor in animal survival. However, marrow aplasia can develop if the earliest stem cells are significantly reduced in number (*1–5*) or are required to proliferate extensively as in the case bone marrow transplantation (*6–10*).

Numerous techniques are currently under study to abrogate the GVH reaction frequently responsible for failure of survival following engraftment of allogeneic hematopoietic stem cells. One such technique entails the use of PNA, a lectin specific for membrane glycoproteins. Following exposure of murine bone marrow to this lectin, separation on a BSA gradient yields two distinct populations of cells: 1) the nonagglutinated fraction, containing mature thymocytes; and 2) the agglutinated fraction, which not only is devoid of GVH activity by virtue of its functionally immature thymocytes but also is enriched with CFU_s (*11–14*). Therefore, the lectin-agglutinated fraction has been advocated as an ideal source of bone marrow for transplantation (*11–13*).

On the basis of the agglutination specificity of PNA to immature but not to mature thymocytes, it was speculated that a similar pattern of lectin separation of hematopoietic stem cells occurs (*12, 13, 15*). The lectin's binding characteristics, as a function of maturity and level of differentiation, have been studied for many different tissues. These data suggest that different tissues vary in their specificity, some with increasing and others with decreasing binding with level of differentiation (*13, 15–17*).

The present study was undertaken to investigate the self-renewal capacity of each of the fractions following lectin separation of bone marrow to determine *a*) whether PNA does separate stem cells on the basis of self-renewal potential and *b*) whether as a related observation certain membrane characteristics may change with maturity of stem cells.

MATERIALS AND METHODS

Donor and recipient animals were 8–12-week-old male inbred C3H/HeJ mice, with 20–26 g body weight (The Jackson Laboratory, Bar Harbor, Maine). Bone marrow cell suspensions were prepared by flushing the medullary cavity of the tibia and femur with PBS. The lectin agglutination, separation, and washing process was that described by Reisner et al. (*11*). suspension of 3×10^8 bone marrow cells in 0.5 ml PBS were incubated with 0.3 ml PNA (Sigma Chemical Co., St. Louis, Mo.), 1 mg/ml for 5 minutes at room temperature. Rabbit erythrocytes, harvested from New Zealand White rabbits in Alsever's solution (GIBCO, Grand Island, N.Y.), were washed in PBS, and 1.8×10^8 erythrocytes in 0.3 ml PBS were added to the bone marrow-lectin mixture and incubated for an additional 2 minutes at room temperature. After the cells were layered onto a BSA gradient (5% wt/vol in PBS), the bottom (agglutinated) and top (nonagglutinated) fractions were harvested separately, and a third tube containing bone marrow cells not exposed to lectin (sham) was added to the experimental regimen. The 3 groups were washed sequentially with 0.2 *M* D-galactose (Sigma Chemical Co., St. Louis, Mo.) in PBS to bind irreversibly to lectin, lysing buffer (a solution of 155 m*M* ammonium chloride, 10 m*M* potassium bicarbonate, 0.01 m*M* EDTA in double-distilled water) to lyse the rabbit erythrocytes and PBS.

ABBREVIATIONS USED: BSA=bovine serum albumin; CFU_s=colony-forming units—spleen; GVH=graft versus host; PBS=phosphate-buffered saline; PNA=peanut agglutinin.

[3] Animals were maintained under the guidelines set forth by the Harvard Medical School.

[4] Joint Center for Radiation Therapy, Department of Radiation Therapy, Harvard Medical School, 50 Binney St., Boston, Mass. 02115.

Cell counts, trypan blue viability, and differential cell counts were then performed, and the cells were injected into irradiated recipients. All irradiation was performed with a ^{137}Cs irradiator with opposing portals to a whole-body dose of 12.5 Gy in divided dose of 7.0 and 5.5 Gy, separated by 3 hours. This split-dose irradiation scheme has been developed in this laboratory to deliver a more marrow-toxic irradiation dose to prevent return of host marrow, while sparing the animal from gastrointestinal death.

In each experiment the cells of each of 4 groups (agglutinated, nonagglutinated, sham, and control) were injected into 8 animals for CFU$_s$ determination 8 days later by the method of Till and McCulloch (*18*) and into 8 animals for transfer. Between 100 and 200 CFU$_s$ were injected into each transfer animal. After a 14-day transfer time, bone marrow cells were harvested from the hindlimb and injected again into 8 animals per group for CFU$_s$ determination.

The self-renewal capacity, R_s was determined by the ratio of CFU$_s$ at the end of the 14-day transfer to the CFU$_s$ initially seeding the hindlimb (*1*): $R_s = S_n/KS_i$, where S_i is the number of CFU$_s$ injected, S_n is the number of CFU$_s$ per hind limb at the end of the transfer, and K is a correction factor on the proportion of seeding stem cells that seed the hindlimb. Because the hindlimb has approximately 10% of the functional bone marrow, the factor is assumed to be 0.1. It is constant for every R_s determination, and therefore its actual value has no qualitative effect on the results decribed. There is in our experience a linear relationship that allows accurate comparison of R_s values over a broad range of injected CFU$_s$ of 50–200, and animals given injections for transfer received CFU$_s$ numbers within this range. Previous results have shown that R_s calculations can detect different self-renewal capacities under different physiologic and pharmacologic states (*1, 2, 19*). A low R_s means that there are few CFU$_s$ harvested 14 days after transfer of 50–200 CFU$_s$, whereas a high R_s means that there are many.

RESULTS

Five separate experiments were analyzed for yield and CFU$_s$ assay. In four of the five experiments, transfer was performed and R_s was calculated. To sample pure cell populations, numerous cells were left in the central portion of the BSA gradient because they were not in the well-demarcated agglutinated segment or in the narrow band of clearly nonagglutinated cells at the top of the tube. This technique following lectin separation and multiple serial washes resulted in 6.6% of the cells in the agglutinated fraction and 7.6% in the nonagglutinated fraction (table 1). These yields account for approximately 14% of the initial cells and CFU$_s$ used. These fractions have been intentionally selected because they demonstrate the extremes of bound and unbound cells most likely to reveal any physiologic difference, including GVH activity. The yields are not particularly practical for transplantation, but they are representative of maximal separation of a functionally heterogeneous stem cell pool. Enrichment of CFU$_s$ in the agglutinated fraction to a mean level of 119% of control, as opposed to a depression of the nonagglutinated fraction to a mean level of 73% of control (P=0.03), was noted. The mean relative enrichment of 1.83 was therefore seen. The CFU$_s$ of the sham group was essentially equal to that of the control. Trypan blue viability of all fractions revealed 90% or more of each fraction's cells to be viable. Differential cell counts of each fraction revealed no significant difference in distribution of elements.

TABLE 1.—*Results of lectin separation: Yield, trypan blue viability, and CFU$_s$ of bone marrow stem cells*[a]

Group	Yield, %[b]	Trypan blue viability, %	Total CFU$_s$	CFU$_s$/10^5	Control CFU$_s$/10^5, %
Agglutinated	6.6±1.5	90	2,454±525	15.5±1.0	119±5[c]
Nonagglutinated	7.6±1.6	95	1,537±298	9.2±1.4	73±13[c]
Sham	60.6±9.5	90	—	12.4±0.6	96±5
Control	—	95	—	13.0±0.7	—
Relative enrichment[d]				1.83±0.[illegible]	

[a] Results of five experiments are means ± SE.

[b] Percent of original cell pool prior to manipulation.

[c] P=0.03, determined by Student's t-test.

[d] Relative enrichment-agglutinated CFU$_s$/10^5 per nonagglutinated CFU$_s$/10^5.

TABLE 2.—*Results of lectin separation: Self-renewal capacity of bone marrow stem cells*[a]

Group	No. of CFU$_s$		Self-renewal capacity	
	S_i[b]	S_n[c]	R_s	Control R_s[d]
Agglutinated	123±9	220±35	18.9±4.9	66.8±10.5
Nonagglutinated	176±23	795±128	45.1±5.2	166±13.6
Sham	122±6	291±68	24.5±7.6	84.5±17.5
Control	132±8	368±57	28.6±5.8	100

[a] Results of four experiments are means ± SE.

[b] S_i=No. of CFU$_s$ injected in hindlimb.

[c] S_n=No. of CFU$_s$ per hindlimb at end of transfer.

[d] P-values were determined by Student's t-test: agglutinated vs. nonagglutinated, 0.01; agglutinated vs. control, 0.05; nonagglutinated vs. control, 0.15; and sham vs. control, 0.55.

Table 2 demonstrates that similar S_i were used for transfer in all 4 groups. It also reveals the results of R_s from four different experiments. The mean percent control R_s of the agglutinated fraction was 66.8%, and that of the nonagglutinated fraction was 166% (P=0.01). The former was statistically different from the control, while the latter were not.

DISCUSSION

Peanut agglutinin, a lectin that is specific for D-galactosyl-β-(1→3)-N-acetyl-D-galactosamine, has demonstrated ability to separate thymocytes according to level of maturity (*11, 14*). The present study reveals significant CFU$_s$ enrichment of the agglutinated fraction. Of great interest is the self-renewal of the agglutinated fraction, which is significantly below normal. In contrast, that of the nonagglutinated fraction is significantly above that of the agglutinated one.

These results indicate that lectins separate pluripotent stem cell fractions with differing proliferative potential. This finding is further evidence of the heterogeneity of the stem cell pool, with regard to self-renewal capacity (*1*). Stem cells progress from a state of great self-renewal potential to that of a lower self-renewal potential, concomitant with an increased proliferative activity and greater commitment to differentiation (*1*). This progression through the stem cell compartment appears to be irreversible. These data suggest that the progression is accompanied by changes in membrane characteristics responsible for differential agglutination by PNA of the more committed and therefore more proliferately active stem cells.

An intriguing alternative to explain the varying self-renewal is the conveyance of a higher self-renewal potential to the nonagglutinated fraction by the presence of mature thymocytes, and a lower self-renewal potential of the agglutinated fraction by the absence of mature thymocytes. While previous data in the literature have suggested a role for T-cells or regulatory cells in CFU_s production (*20–22*), consistent data to support this have been lacking (*23*). A complex relationship may actually exist, with relative concentrations of T-cell and/or regulatory cell subtypes as the determining factor. Work is currently under way in this laboratory to investigate these possibilities. Even if this factor is in some way related to the varying self-renewal of the lectin fractions, the practical importance in bone marrow transplantation is still the lower self-renewal potential of the agglutinated fraction.

Stem cell enrichment is not an appropriately defined goal. This population is a continuum of cells, and what is sought is enrichment of those with the greatest proliferative capacity. Measure of stem cell numbers without regard to quality may, as in the case of PNA, be misleading. These data suggest that the use of the agglutinated fraction for bone marrow transplantation, despite its enrichment with CFU_s and lack of GVH activity, may carry a significant risk of subsequent marrow failure.

Immunologic Relatedness of Intracisternal A-Particles in Mouse Embryos and Neoplastic Cell Lines[1,2,3]

Thomas T. F. Huang, Jr.,[4,5] *and* **Patricia G. Calarco**[4,6,7]

ABSTRACT—Murine intracisternal A-particles (IAP) are retroviruses expressed in large numbers in certain neoplastic cells and preimplantation mouse embryos. Immuno-electron microscopic detection of IAP-associated antigens in mouse rhabdomyosarcoma cells and early mouse embryos provides the first direct evidence that IAP produced by these two sources are serologically related. In both embryos and cells, data suggest that, after synthesis, IAP core protein rapidly associates with the endoplasmic reticulum. In addition, in embryos only, data confirm earlier observations that IAP-associated antigens are expressed on the cell surface. There is no evidence that the Golgi apparatus is involved in the processing of IAP antigens in either cell type.—JNCI 1982; 68:648–649.

Murine IAP are retrovirus particles that form by budding from the cytoplasm into the ER in certain neoplastic and normal cells of *Mus musculus* (*1*). For example, IAP occur in large numbers within plasmacytomas (*2*) and diverse tumors derived from all three germ layers (*3*). In contrast, IAP are rarely seen in normal adult tissues (*3*). However, IAP appear in large numbers during early preimplantation mouse embryogenesis, when their production is regulated as part of normal embryonic development (*4–7*). IAP appear between the two- and eight-cell stage but are diminished or absent in morulae and blastocysts. The appearance of IAP during early development has been noted also in two Asian mouse species, *M. pahari* and *M. cervicolor* (*8*).

Biochemical and serologic studies of IAP isolated from neoplastic sources (*9–11*) have demonstrated that IAP genetic information is endogenous to and highly reiterated within the *Mus* genome. There is also strong serologic evidence that IAP expressed in different neoplastic cells are related through a common core protein antigen (*12*). The relatedness of embryo IAP and IAP produced in tumor cells has not been determined. Because sufficient numbers of embryo IAP are difficult to obtain for making a biochemical comparison with IAP from neoplastic cells, we have undertaken a serologic approach using an antibody prepared against IAP purified from the MOPC 104E plasmacytoma (*13, 14*). We report here, using IEM techniques, that IAP produced in preimplantation mouse embryos are immunologically related to IAP produced in a neoplastic cell line.

MATERIALS AND METHODS

Embryos and culture.—Two-cell embryos were obtained from superovulated, pregnant female ICR mice (Simonsen Laboratories, Gilroy, Calif.) and cultured to the appropriate stages by the methods of Biggers and Stern (*15*). Zygotes were obtained from similar females a day earlier. Unfertilized eggs were obtained from superovulated, unmated females.

Antibodies.—The IAP used as the immunogen were prepared from MOPC 104E cells and provided to us by Dr. Nelson Wivel (NCI, Bethesda, Md.). One-dimensional gel analysis of these IAP revealed that they consisted primarily of a 73,000-dalton protein. Anti-IAP was prepared in rabbits by standard procedures and was characterized as follows [*see* (*13, 14*) for details]: Anti-IAP reacted as a single precipitin band against IAP in one-dimensional rocket electrophoresis. IIF and peroxidase-antiperoxidase staining of acetone-fixed cell lines demonstrated anti-IAP reactivity against cell lines producing IAP. In cell lines not producing IAP, no reactivity against other cellular components, e.g., ER, was observed. In addition, live embryos examined by IIF and immunoradiolabeling expressed IAP antigens on their cell surfaces whereas cell lines did not (*13*). In immunoprecipitation and gel analyses of labeled cell lines producing IAP, anti-IAP recognized primarily a protein of 73,000 daltons. Protein bands of 73,000, 69,000, and 67,000 daltons, which correlated with the stage-specific appearance of IAP, were also precipitated from labeled embryos (*14*). Absorption with the IAP immunogen removed the activity of the anti-IAP in all the assays described above. Goat anti-rabbit IgG conjugated to HRPO was obtained from Miles Chemical Co. (Elkhart, Ind.) and stored in frozen aliquots.

RMS cells and culture.—RMS cells (courtesy of Dr. John Dahlberg, NCI) were grown in four-well Lab-Tek chamber slides (Miles Chemical Co.) in Dulbecco's modified Eagle's minimum essential medium supplemented with 10% fetal calf serum. When cells were between 60 and 70% confluent, they were used in experiments.

IEM.—Tissues were fixed at room temperature. Embryo

zonae pellucidae were either digested with pronase (0.5%, 5 min in culture medium) or removed mechanically by extrusion through a small-bore micropipette. Embryos were then allowed to recover in culture medium for at least 2 hours. After being rinsed in Dulbecco's PBS, they were fixed in 0.05% glutaraldehyde in PBS (pH 7.0, 5–15 min) and then rinsed three times in PBS over 30 minutes. RMS cells were treated as monolayers in the chamber slides in which they were grown and processed as described above.

An indirect immunoperoxidase staining protocol was used as adapted from Willingham et al. (*16*). Antibody dilutions and rinses consisted of saponin buffer [Ca^{2+}- and Mg^{2+}-free Dulbecco's PBS plus 0.5% saponin (Sigma Chemical Co., St. Louis, Mo.), 1.0 m*M* ethyleneglycol-bis(β-aminoethyl ether)N,N′-tetraacetic acid, and 5.0 mg normal goat globulin/ml]. The normal goat globulin was prepared by the precipitation of normal goat serum twice with 50%-saturated ammonium sulfate. Embryos were treated as follows: 1) incubated in saponin buffer, 30 minutes; 2) incubated in first antibody (anti-IAP or NRS IgG at 0.05 mg/ml), 1.0 hours; 3) rinsed three times in saponin buffer, 1.0 hour total; 4) incubated in goat anti-rabbit IgG conjugated to HRPO (1/80 dilution), 1.0 hour; and 5) rinsed in saponin buffer, 1.0 hour. For development of the peroxidase reaction, cells or embryos were placed in 50 m*M* Tris buffer (pH 7.6, 15 min) containing 3,3′-diaminobenzidine (0.05 mg/ml) and hydrogen peroxide (0.02%). After being rinsed in 50 m*M* Tris buffer for 10 minutes, the reacted material was fixed secondarily for 15 minutes in 3.0% glutaraldehyde in 0.1 *M* phosphate buffer, containing 2.5% sucrose, then postfixed 15 minutes in 2% osmium tetroxide in 0.1 *M* phosphate buffer.

Fixed and reacted embryos were dehydrated in alcohol. After dehydration, the alcohol was exchanged with propylene oxide and then the embryos were embedded in Epon-Araldite. RMS cells were dehydrated in alcohol and infiltrated with Epon-Araldite directly (two changes over 24 hr at room temperature followed by a final change and subsequent hardening at 56°C for 48 hr). Thin sections were examined without being counterstained on a Hitachi HS-8 electron microscope.

RESULTS

The procedures for IEM examinations outlined here preserved sufficient ultrastructure for localization of IAP antigens in cell lines and embryos. In initial titration experiments, RMS cells were first fixed in 0.05% glutaraldehyde, and their membranes were then made permeable by treatment with 0.5% of the glycoside, saponin, which permitted antibody reagents to reach the ER. Other procedures such as primary fixation by 1.0% 1-ethyl-3(3-dimethylaminopropyl)-carbodiimide (Sigma Chemical Co.) together with 0.2% glutaraldehyde followed by saponin (*17*) did not allow antibody to penetrate into the matrix of the ER.

On comparison with the conventional preparation of embryos for EM examinations (*4*), our adapted procedure sufficiently preserved many cellular structures. We could resolve nuclei, mitochondria, fibrous material, ER, Golgi cisternae, and associated vesicles. However, artifacts such as whorled myelin-like structures and areas of apparent extraction were noted frequently. In general, preservation of unfertilized eggs, zygotes, and trophoblast cells was significantly improved when the primary fixation time was increased from 5 to 15 minutes.

RMS cells produced large numbers of IAP, and immunostaining of RMS cells with anti-IAP IgG was strong over the ER (fig. 1). Higher magnification allowed us to visualize discrete virions within the ER cisternae (fig. 2). Often the density of oxidized DAB obscured the virion's doughnut-like morphology, and the entire cisterna was darkened. In addition, limited areas of the nuclear envelope were lightly stained in regions near budding virions (fig. 2), whereas other areas of this membrane appeared free of reaction product. Occasionally, IAP were visible between the leaflets of the nuclear envelope (fig. 2). Neither Golgi cisternae nor associated vesicles showed staining (fig. 5). No IAP were observed free in the cytoplasm or budding from the plasma membrane. Control experiments with normal rabbit IgG showed no DAB deposits in the regions of IAP, ER, or in the nuclear envelope (figs. 3, 4).

If naturally occurring embryo IAP are related immunologically to the IAP produced by neoplastic cells, then embryo virions should also stain with our anti-IAP which was prepared against IAP from MOPC 104E. In fact, two- to eight-cell embryos demonstrated immunostaining for IAP antigens in regions where virions formed within the ER (figs. 6, 7). This immunostaining was often more diffuse than the staining seen in RMS cells, and there was some variation in the intensity with which individual IAP were stained. These IAP appeared to possess the small central core (≈30 nm) characteristic of small A-particles (*7*) or ε-particles (*18*). This may account for the observed staining differences because IAP from cell lines are exclusively of the "large A-type" with a central core of approximately 50 nm (*7*). Golgi regions did not exhibit reaction product (fig. 8), nor was there evidence of IAP antigen association with the nuclear envelope. Neither was there reaction product within ER cisternae of later embryo stages such as the blastocyst. Interestingly, IAP antigens were detected on the plasma membrane from the zygote to the eight-cell stage (fig. 6). Control experiments with NRS IgG revealed no staining over IAP, the ER, or the cell surface (fig. 9).

DISCUSSION

The results presented here outline a procedure for fixing embryos and cell lines and for making them permeable so that antigens within the ER could be localized. We have adapted the EGS[8] procedure introduced by Willingham et al. (*16*) to detect cytoplasmic antigens. Although the original method apparently cross-links the ER in a manner that prohibits antibody access to this compartment, a primary fixation in which more dilute aldehyde is used (Willingham MC: Personal communication) combined with increased concentrations of saponin results in satisfactory penetration of antibodies into the ER of cell lines grown as monolayers.

[8] 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide-glutaraldehyde-saponin.

Using this modification, we report data here that provide direct evidence that IAP naturally expressed in mouse embryos are serologically related to those expressed in tumor cells.

Several investigations have helped to clarify the cellular events involved in retrovirus formation and maturation, at least in the C-virus system. The preponderance of avian C-type virus core polyprotein is synthesized on cytoplasmic rather than membrane-bound polyribosomes (*19*). Other studies in which temperature-sensitive murine leukemia viruses were used indicate that core polyproteins rapidly associate with the cytoplasmic face of the plasmalemma (*20, 21*). This association involves a stringent recognition event between the core polyprotein and the viral envelope gene product (*22*) that has previously integrated into the plasmalemma. Results from the IAP system are consistent with the C-virus model with two exceptions: Production of an IAP envelope gene product has never been reported, and the IAP core protein associates with the membrane of the ER rather than with the plasmalemma. In embryos, IAP antigens associate with and bud into the agranular ER at the two-cell stage before the association of ribosomes with the ER. This observation suggests that synthesis of IAP proteins also occurs on cytoplasmic (free) polyribosomes, although we have not been able to detect IAP antigen(s) in the cytoplasm before their incorporation into recognizable IAP. However, the 73,000-dalton IAP major core protein (p73) has been shown to be synthesized on membrane-bound ribosomes in MOPC 104E cells (*23*). One resolution of these observed differences may be that embryos synthesize IAP antigens in a different manner than do transformed cell lines. We do know that IAP antigens are expressed on the cell surface of embryos but not MOPC 104E cells (*13*).

In RMS cells, IAP antigens are localized primarily over the IAP and the ER cisternae and occasionally on the NE. This finding is consistent with results obtained from conventional EM studies that indicate that IAP form by budding into the ER, where they often remain attached (*24*). It is not surprising to observe the association of IAP antigens with the NE because the NE is considered to be derived from the ER (*25*). IAP have not been seen free in the cytoplasm or budding externally from IAP-producing neoplastic cells. In addition, we find no evidence that IAP antigens migrate to the Golgi region or to the surface of RMS cells. This observation is consistent with the observation by Kuff et al. (*12*) that IAP antigen is not found in the culture medium of neoplastic cells producing IAP. Moreover, IIF studies (*13*) do not detect IAP antigens on the surface of living, IAP-producing neoplastic cell lines.

However, our previous IIF work indicated that IAP-associated antigens *are* expressed on the surfaces of early embryos, in contrast to IAP antigen expression on IAP-producing neoplastic cells (*13*). The present study confirms these observations at the EM level. Because there is no evidence that the Golgi apparatus is involved in processing embryo IAP antigens, IAP antigens may be transported to the plasmalemma directly by the ER or they may enter from the cytoplasm without prior membrane association. This latter strategy is utilized by M13 coliphage procoat protein [*see* (*26*)].

Our previous work has shown that p73 is the major constituent of the immunogen used to prepare anti-IAP (*13*). With our anti-IAP, immunoprecipitation and gel analysis of early embryos reveal the p73 core antigen and two other antigens (67,000 and 69,000 daltons) that correlate directly with IAP presence (*14*). The IEM approach reported here may be detecting all three of these antigens. Surface labeling studies are in progress to determine which antigen(s) are expressed on the cell surface.

Although surface expression of the p73 core protein would be unusual, there are precedents for the surface expression of core protein antigens of other retroviruses (*27–29*). To account for this in molecular terms, Edwards and Fan (*30*) have studied Moloney murine leukemia virus-infected fibroblasts and present evidence for the synthesis of two primary translation products bearing core polyprotein antigen. One translation product, of 65,000 daltons, remains unglycosylated and is processed to form smaller mature virion core components. A second primary translation product of 75,000 daltons is glycosylated before its insertion into the cell surface. Although conjectural, the 75,000 component could contain a leader or signal sequence (*26, 31*) that determines radically different processing of otherwise similar information.

The biologic role, if any, for IAP information in the etiology of cancer or in the normal process of development remains conjectural. The IEM study reported here provides direct evidence that IAP from a neoplastic tissue are immunologically related to IAP appearing in normal development. This evidence increases the likelihood that more specific molecular probes derived from neoplastic cells, such as cloned nucleic acid sequences (*10, 11*), may be used to study further the processing of IAP information during normal development.

Methylazoxymethanol: Effect on the Immune Response of Rats to Human Serum Albumin[1,2,3]

Ahmed F. S. A. Habeeb,[4] **Alan M. Preston,**[4] **Priscila Sanabria,**[5] *and* **Nelson Escobales**[5]

ABSTRACT—Inbred male F344 rats treated with 20 mg methylazoxymethanol (MAM)/kg body weight showed minimal damage to DNA in bone marrow, spleen, and thymus and no suppression of the humoral immune response to human serum albumin (HSA). At high doses of MAM (40, 60, and 80 mg/kg), damage to DNA of bone marrow, spleen, and thymus was noted. The effect on the humoral immune responses was nonuniform. Some rats responded normally by eliciting precipitating antibodies, whereas others responded by synthesizing nonprecipitating antibodies at low levels. The production of nonprecipitating antibodies may indicate a restriction of the recognition of HSA antigenic determinants in rats given injections of MAM prior to immunization. The restriction may be a consequence of suppression or elimination of certain clones of lymphocytes responsible for recognition of certain antigenic determinants. This interference in some clones of lymphocytes would result in the synthesis of antibodies against one or two antigenic sites on the HSA and the concomitant inability of the produced antibodies to form complete lattice structure with antigen.—JNCI 1982; 68:651–656.

MAM, the aglycone moiety of the glycoside cycasin, has been found to be a potent carcinogen (*1*), mutagen (*2*), and hepatotoxin (*3*). Its tumorigenic effect has a broad spectrum. Neoplasms have been induced by MAM in the digestive tract (*4*), liver (*5*), lung (*6*), kidney (*7*), and brain (*8*) and in various species including rats (*9*), mice (*10*), guinea pigs (*11*), hamsters (*8*), and fish (*12*). In its manner of action, MAM belongs to the family of indirect-acting chemical carcinogens. The ultimate carcinogen generated from it is the highly reactive carbonium that alkylates guanine in several positions (N-7 and O-6 preferentially) (*13*).

Chemical carcinogens exert a variety of effects on the cells of the immune system (*14*). Several powerful carcinogens interfere with both cellular (*15*) and humoral (*16, 17*) immune responses. It is highly likely that the interactions of some chemical carcinogens with cells of the immune system result in the interruption of the function and ability of the immune system to respond to antigens without a neoplastic transformation having necessarily to occur.

However, if damaged, cells possess a mechanism for the repair and restoration of the integrity of the DNA molecule and the preservation of the fidelity of the transformation encoded in it (*18*). This DNA repair mechanism has been studied with the use of lymphocytes and has been found to be operative in them (*19*). This phenomenon suggests that chemical carcinogens can interact with the DNA of lymphoid cells and that the cells make an effort to repair the effects of this encounter.

The purpose of the investigation was to determine the effect of MAM at various doses on the humoral immune response of rats given injections of HSA and to determine the degree and rate of interaction of MAM with the DNA of the immunocompetent cells, as well as the rate of DNA repair synthesis.

MATERIALS AND METHODS

HSA, fatty acid-free, was supplied by Sigma Chemical Co. (St. Louis, Mo.). Bacto CFA was purchased from Difco Laboratories (Detroit, Mich.). MAM was supplied by Schwartz/Mann Div., Becton, Dickinson & Co. (Orangeburg, N.Y.), and [*methyl*-^{3}H]thymidine (sp act, 71.5 Ci/mmol) was purchased from ICN Pharmaceuticals Inc. (Cleveland, Ohio). Inbred male F344 rats were supplied by Charles River Breeding Laboratories (Wilmington, Mass.).

Immunoelectrophoresis.—Immunoelectrophoresis was performed on a projector slide cover glass 3¼×4 inches coated with a film of agarose [18 ml of 1.5% agarose in barbital buffer, μm = 0.05 (pH 8.4), containing 1:10,000 merthiolate]. Antisera from MAM-treated and immunized rats were placed in the central well and electrophoresed at 15 mA/plate for 90 minutes. Precipitin lines were allowed to develop for 24 hours after the addition of the antigen (HSA at 0.12 mg/ml) to the troughs. The plates were washed in saline, dried, and stained with Ponceau S (0.15% in trichloroacetic acid); they were then washed with 7% acetic acid and dried.

Double diffusion in agar.—Into a petri dish was poured 15 ml of 1% Noble agar in buffered saline (pH 7.2) containing 1:10,000 merthiolate. The agar was left to cool and aged for 1 day at room temperature. Wells were punched with a cork borer, the two central rows were filled with HSA solution, and the two peripheral rows were filled with 20 μl of antisera from MAM-treated and immunized rats. The dishes were placed in a moist atmosphere for 24 hours at room temperature for development of precipitin lines. This method afforded a rapid and sensitive method to screen numerous antisera for the appearance of anti-HSA antibodies from MAM-treated and immunized rats.

Quantitative precipitin test.—To 0.2 ml of a twofold increasing concentration of HSA in PBS was added 0.2 ml of antisera from MAM-treated and immunized rats. The mixtures were incubated at 40°C for 1 hour and then overnight at 4°C. The tubes were centrifuged and the precipitate was

washed twice with saline. The precipitate was dissolved in 0.2 ml 5% sodium dodecyl sulfate and 1 ml of water (*20*) and then mixed with 3 ml of reagent C of Lowry et al. (*21*). After the mixture stood for 20 minutes, 0.3 ml of Folin phenol reagent was added and the absorbance was read at 750 nm. The absorbance reading was converted to milligrams of antibody per sample by reference to a standard curve constructed by the subjection of known quantities of rabbit IgG to the same color reaction.

Preparation of Sepharose–HSA immunoabsorbent.—To quantitate the total antibody in the sera of MAM-injected and HSA-immunized rats and to detect nonprecipitating antibodies that would escape detection by the precipitin test, we used a Sepharose–HSA immunoabsorbent. We prepared the immunoabsorbent by conjugating HSA to activated Sepharose 4B. Sepharose 4B was activated by an acetonitrile solution of cyanogen bromide in 1 *M* Na_2CO_3 (*22*). To a solution (50 ml) of HSA in 0.1 *M* sodium phosphate buffer (pH 8; 3 mg/ml) was added 30 g of activated Sepharose, and the mixture was blended by gentle agitation for 18 hours at 4°C. The amount of protein conjugated was determined from the difference in concentration before and after reaction with activated Sepharose (determined from absorbance at 280 nm). After reaction, excess activated groups were blocked by mixing with gentle agitation the Sepharose cake with 50 ml of 0.5 *M* glycine in 0.1 *M* sodium phosphate buffer (pH 8) for 3 hours. The suspension was filtered and washed with 0.1 *M* sodium acetate, 2 *M* urea, 0.1 *M* $NaHCO_3$ (pH 10), water, and finally with PBS (pH 7.2). The Sepharose–HSA immunoabsorbent contained 3.25 mg HSA/ml packed immunoabsorbent.

Determination of antibody on Sepharose–HSA immunoabsorbent.—To 3 ml of packed immunoabsorbent in a glass column (1×20 cm) was added 0.15–0.3 ml of antiserum diluted with 2.5 ml PBS. The mixture was whirled thoroughly by a vortex mixer and then incubated at 4°C for 18 hours, after which the column was drained of and the immunoabsorbent was washed with PBS (pH 7.2; collecting 3.7 ml/tube) until absorbance reached 0.01. (This procedure required about 7–8 tubes.) Then the antibody was dissociated by the column's being washed with 5 *M* guanidine until absorbance was 0.01. The eluted antibody was monitored at 280 nm, and the pooled antibody was dialyzed twice against water and then against PBS. From the volume and the antibody content per milliliter [determined by the Lowry method; Lowry et al. (*21*)] the total amount of antibody per milliliter of antiserum was calculated.

Animal treatment and experimental protocol.—DNA repair studies: Male F344 rats weighing about 100 g received injections three times ip of 150 μCi [^{3}H]thymidine at 16, 4, and 0 hr before injection with MAM with the use of doses of 20, 40, or 60 mg/kg body weight. Animals were killed 2 per trial at 0, 2, and 18 hours after injection of MAM, and the femur, spleen, and thymus were dissected Marrow was collected by aspiration of the femur with a syringe. Suspensions of spleen and thymus cells were obtained by means of the squash technique (*23*). DNA repair was monitored with the use of sedimentation techniques through 5–20% alkaline sucrose gradients in which DNA from cells lysed on the gradient permitted detection of DNA damage (*23*). From 0.1 to 0.3 ml of cells consisting of approximately 1 μg DNA that contained about 300–700 cpm was added to each gradient.

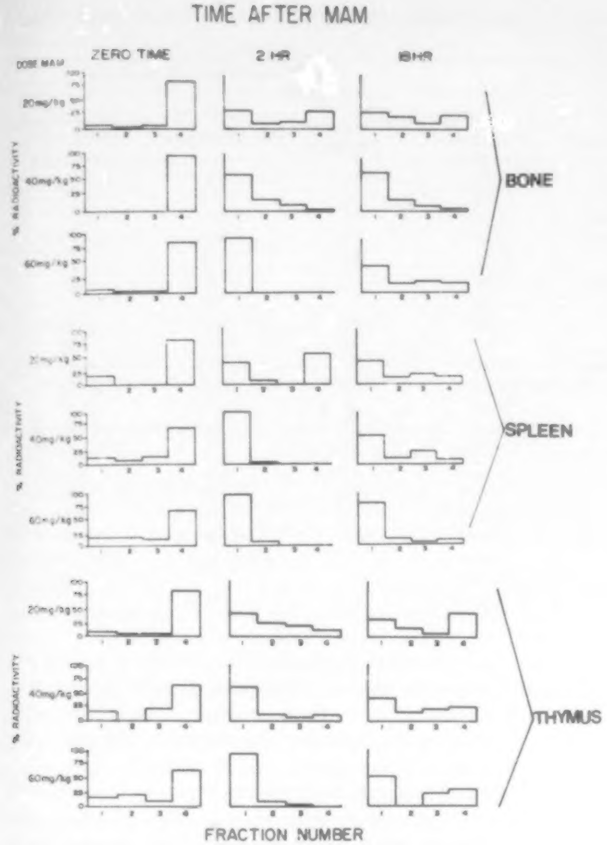
The lysed cells were centrifuged at 45,000×*g* in a type 40 rotor for 30 minutes at 20°C by means of a model L3-50 preparative ultracentrifuge (Beckman Instruments, Inc., Fullerton, Calif.). Fractions of 1.2 ml each were collected by means of a gradient fractionator (ISCO, Lincoln, Nebr.). In this method. the first fraction contained the 5% portion of the gradient. Bovine serum albumin was added to each fraction before precipitation with trichloroacetic acid. Each precipitate was solubilized (NCS solubilizer; Amersham/Searle Corp., Arlington Heights, Ill.) after which scintillation fluid was added (Aquasol II; New England Nuclear Corp., Boston, Mass.) and the radioactivity was determined in a liquid scintillation counter (Beckman Instruments, Inc.).

Immunologic studies: A group of male F344 rats were given injections ip of 0.1–0.3 ml MAM (7.0 mg/ml saline) so that each rat received 20 mg/kg body weight or saline alone (controls). Then after 0 hours, 2 hours, 12 hours, 24 hours, 3 days, and 7 days, a subgroup of 6 rats received injections im of 1 mg HSA emulsified in CFA (0.2 ml). Three weeks later a second injection of HSA (similar to the first) was given, and then the rats were bled (2 ml blood) through the heart 2 weeks later and thereafter at weekly intervals for 3 weeks. Other groups of rats received injections ip of MAM in saline so that the dose received was 40, 60, and 80 mg MAM/kg body weight. Control rats received saline alone. Then after 0 hours, 2 hours, 18 hours, 3 days, and 7 days, a subgroup of 4 rats received injections of 0.2 ml of HSA emulsified with CFA (containing 1 mg HSA). Three weeks later, the rats received a similar injection of HSA, and then 2 weeks after the second injection they were bled (2 ml blood) through the heart. The blood was collected in tubes treated with EDTA to prevent clotting. Plasma was decanted after centrifugation and preserved with merthiolate at 1:10,000. Controls were included consisting of rats immunized without prior MAM treatment and rats treated with MAM without immunization. To ascertain the immune responses of MAM-treated rats to injection of HSA, we determined the antibody both qualitatively by immunoelectrophoresis and double diffusion and quantitatively by the precipitin test and on an immunoabsorbent.

RESULTS

DNA Repair Studies

Damage to DNA was dose related, being minimal at 20 mg/kg and maximal at 60 mg/kg in all tissues studied (text-fig. 1). A low amount of damage was seen at zero time, maximum damage occurred after 2 hours, and some repair synthesis was noted after 18 hours (text-fig. 1). Some breakage was observed due to handling techniques as indicated by the height of the left-hand bar at zero time. The degree of this damage varied with individual tissues, being low with bone (6%) and higher with spleen (10–18%) and thymus (7–17%).



TEXT-FIGURE 1.—Effect of ip injections of MAM acetate at three dose levels (20, 40, and 60 mg/kg) on DNA of bone marrow, spleen, and thymus of rats killed at time of injection and 2 and 18 hr after injection with MAM. Histograms are based on sedimentation profiles of alkaline sucrose gradients from rats receiving 3 doses of 150 μCi each of [^{3}H]-thymidine 16, 4, and 0 hr before injection with MAM. The text-fig. was prepared so that the left-hand bar represents pooled samples of the lightest DNA fraction and each successive bar represents pooled samples of progressively heavier fractions.

Qualitative Determination of Antibody Response

All plasma from 20-mg/kg MAM-treated and HSA-immunized rats was screened for antibody by immunoelectrophoresis. However, this procedure was replaced by double diffusion in agar as a simple and rapid screening procedure for detecting precipitating antibody in rats immunized at 0 hours, 2 hours, 12 hours, 24 hours, 3 days, and 7 days after MAM treatment. Table 1 summarizes the responses of MAM-treated rats to immunization with HSA. All rats responded by production of antibodies. Table 2 shows the responses of rats given injections of MAM (40, 60, and 80 mg/kg body wt) prior to immunization by HSA as demonstrated by Ouchterlony. In the group of rats given injections of 40 mg MAM/kg body weight, all rats (that received injections of MAM 0, 2, and 18 hr before HSA immunization) responded by producing antibody. Conversely, plasma of some of the rats that were given injections of MAM 3 or 7 days before HSA immunization showed no precipitation in an Ouchterlony plate. This lack of precipitation may have been due either to absence of antibodies or to the presence of nonprecipitating antibodies.

In the group of 20 rats that were given injections of 60 mg MAM/kg body weight, 4 rats died (20%), 6 (30%) did not respond as shown by absence of precipitin lines, and 10 (50%) had precipitating antibodies. There was no apparent correlation between the formation of precipitin lines and the time between MAM injection and HSA immunization. In the group of 20 rats receiving injections of 80 mg MAM/kg prior to immunization, the mortality was considerable; 13 rats died (65%). In addition, 5 rats (25%) produced precipitating antibodies, whereas 2 (10%) produced nonprecipitating antibodies.

Quantitative Determination of Antibody Response

Because of the limited quantity of plasma from rats that were treated with 20 mg MAM/kg body weight, immune plasma from the first, second, and third bleedings of 2 rats was pooled and used for quantitative precipitin reaction (table 3). The value of antibody (mg/ml) plasma was that obtained at the equivalence point. The amount of antibody varied greatly among the individual rats in a given subgroup, which precluded any conclusion apart from the fact that MAM treatment (20 mg/kg body wt) prior to immu-

nization did not suppress the antibody response and was not affected whether MAM was given 0–7 days prior to immunization. If the values of the antibody of a subgroup are averaged (which represents 18 plasma samples from 6 rats and three bleedings), then there appears to be some potentiation of the humoral immune response by MAM; however, differences were not statistically significant.

[b] *Numbers in parentheses* are means of antibody level (mg/ml plasma) from a subgroup of rats.

In 19 rats (table 4) that received injections of 40, 60, and 80 mg MAM/kg body weight prior to immunization, the antibody level that gave precipitin lines in Ouchterlony was similar to the antibody level in the controls shown in table 3. However, 9 rats whose plasma did not give precipitin lines produced nonprecipitating antibodies that were trapped and recovered on the immunoabsorbent. The level of nonprecipitating antibodies in those 9 rats was quite variable. The variation did not seem to be dependent on the dose of MAM injected. Five rats produced a low level of nonprecipitating antibodies (0.33–0.89 mg antibody/ml plasma), while 4 rats had a higher level (1.08–2.88 mg antibody/ml plasma) that was of the same magnitude as that of the precipitating antibody produced in rats given 40, 60, and 80 mg MAM/kg body weight prior to immunization. It is evident that injection of MAM (at 40, 60, and 80 mg/kg) prior to immunization of rats with HSA evoked a variable spectrum of effects on the humoral immune response. In some rats the humoral immune response was unaffected and the rats responded by producing precipitating antibodies; other rats elicited nonprecipitating antibodies at a level similar to that of the controls, and still other rats had a depressed level of nonprecipitating antibodies.

DISCUSSION

MAM acetate can cause damage to DNA of the liver, kidney, and small intestine of rats (*24*, *25*). Moreover, Damjanov et al. (*13*), using doses of 25 mg MAM/kg body weight, reported that after 14 days damage to liver DNA

[a] *Numbers in parentheses* indicate that the value was from rat that gave no precipitin lines in Ouchterlony.

had not been repaired. It is not surprising, therefore, that the equivalent and higher doses of MAM used in the present experiment caused damage to DNA in bone marrow, spleen, and thymus that persisted after 18 hours. That the repair in these tissues is dose related is also expected because it is well documented for other tissues (*13*).

Zedeck et al. (*26*) postulated that changes necessary for tumor growth occur soon after treatment with MAM. One of the purposes of the current study was to determine if MAM had a direct and immediate effect on immunocompetent cells. Although damage to the DNA of the bone marrow, spleen, and thymus of rats was noted, there was little humoral immunosuppression as measured by response to injection of HSA.

At low doses of MAM (20 mg/kg), there was no suppression of the immune response of rats against the injection of HSA. Conversely, with rats treated with high doses of MAM (40, 60, and 80 mg/kg body wt), the mortality increased with an increase in the doses of MAM. Moreover, the antibody responses of rats to HSA were not uniform; many animals that did not show precipitating antibodies responded by synthesizing nonprecipitating antibodies (at variable levels) that were detected by immunoabsorbents.

There is strong evidence that in cases in which nonprecipitating antibodies are produced as a result of antigenic stimulation by complex antigens, the antibodies are formed against one or two antigenic determinants that, on reaction with the antigen, will be incapable of forming a lattice structure necessary for precipitation. Thus guinea pig nonprecipitating antibodies against ovalbumin reacted with ovalbumin at a molar ratio of antibody:antigen of 1.5, which was less than 2.5 shown by antiovalbumin precipitating antibodies (*27, 28*). Similarly, Fab fragments derived from nonprecipitating antiovalbumin antibodies reacted with ovalbumin at a molar ratio of Fab:ovalbumin equals 2 compared to a ratio of 3.2 for Fab fragments derived from precipitating antiovalbumin antibody (*27, 28*). Nonprecipitating antibodies against cobrotoxin reacted at a molar ratio of antibody:antigen equals 0.79–0.97 compared to a value of 1.58–1.94 for precipitating antibodies (*29*). Recently, we showed that pigs elicited nonprecipitating antibodies against chicken egg white lysozyme during the period of immunization that was revealed on lysozyme immunoabsorbent column (*30*). Binding studies on both the nonprecipitating antibodies and Fab fragments derived from them indicated that the molar ratio of antibody or Fab:lysozyme equals 2 compared to a value of 3 for precipitating antibodies (30).

On the basis of these facts, we are proposing that nonprecipitating antibodies to HSA elicited in MAM-treated rats were produced as a consequence of a restriction in the recognition of some of the HSA antigenic determinants so that only one or two antigenic determinants were recognized by the rat's immune system. This limited recognition of HSA antigenic sites may indicate that certain clones of lymphocytes were either suppressed or eliminated as a result of MAM treatment. The outcome of these events would be the formation of antibodies against one or two antigenic determinants of HSA and their concomitant nonprecipitability. Of significance was the finding that MAM in high doses had a varied effect on the rat's humoral immune system so that some animals synthesized precipitating antibodies normally and others showed signs of restriction in their recognition of the antigenic determinants of a complex antigen resulting in the production of nonprecipitating antibodies at different levels. The use of immunoabsorbents was instrumental in trapping and detecting nonprecipitating antibodies. Except for the effects at high (approaching toxic) doses, it would appear that MAM does not inhibit the humoral immune responsiveness.

Peptidoglycans Extracted From Gram-Positive Bacteria: Expression of Antitumor Activity According to Peptide Structure and Route of Injection[1,2]

Anne-Françoise Goguel,[3] Geneviève Lespinats,[3] *and* Charles Nauciel[4]

ABSTRACT—The antitumor effect of peptidoglycans of various structures extracted from different gram-positive bacteria was studied, on chemically induced fibrosarcomas, in C3H/He, C57BL/6, and (C57BL/6 × C3H/He)F_1 mice. When given sc admixed with tumor cells, only some peptidoglycans (those extracted from *Bacillus megaterium* and *Staphylococcus aureus*) enhanced tumor resistance in syngeneic and semiallogeneic hosts, whereas other peptidoglycans (those extracted from *Micrococcus lysodeikticus* and *Corynebacterium poinsettiae*) possessed no antitumor effect. When tumor cells were given ip, administration of peptidoglycans by the same route was either without effect on tumor growth or it induced tumor enhancement. Enhancement could be observed with all of the peptidoglycans tested. The antitumor effect when given sc and the ability to stimulate the proliferation of B-lymphocytes were shared by the same two peptidoglycans, while the other two peptidoglycans were devoid of both activities. It appears that these biological activities depend on the structure of the peptide moiety of peptidoglycans and that mitogenic and antitumor responses are stimulated by similar structures. JNCI 1982; 68:657–663.

Whole bacteria have been widely used to increase tumor resistance. Most such studies have been done with BCG and *Corynebacterium parvum*, but other bacterial species, such as *Bordetella pertussis* (*1*), *Listeria monocytogenes* (*2*), *Streptococcus pyogenes* (*3*), *Brucella abortus* (*4*), and *Staphylococcus aureus* (*5*), have sometimes been used.

In view of obtaining reproducible results and to avoid undesirable side effects, many authors have investigated the possibility of using various bacterial extracts as efficient immunomodulators. Some fractions extracted from mycobacteria [mostly cell walls, interphase material extracted from mycobacteria, methanol-extracted residue from mycobacteria, and cord factor (*6–12*)] or from other bacteria [*Nocardia rubra* (*13, 14*) and *C. parvum* (*15*)] possess antitumor effects in several experimental models.

In a previous report (*16*), we described how the peptidoglycan extracted from the cell walls of *Bacillus megaterium* was able to inhibit the development of a chemically induced fibrosarcoma in rats. The peptidoglycan is the only cell wall polymer common to both gram-negative and gram-positive bacteria. This cell wall extract is a heteropolymer built of glycan strands interconnected through short peptide chains which are cross linked. The glycan moiety of the peptidoglycan is remarkably uniform throughout the bacterial world. It is made up of the repetition of *N*-acetylglucosamine and *N*-acetylmuramic acid connected by β-1,4 linking. The composition and structure of peptidoglycans seem rather constant among gram-negative bacteria, but variations are great among gram-positive bacteria. Among bacterial species, these variations can occur in the structure of the peptide chain and in the nature of the interpeptide bridge (*17*).

Previous studies have shown that bacterial peptidoglycans can exhibit adjuvant activity on cellular and humoral responses (*18, 19*) and can possess mitogenic effects (*20*). It was also established that variations in the structure of the peptide moiety are correlated with changes in the adjuvant and mitogenic properties of peptidoglycans. (Guenounou M, Goguel AF, Nauciel C: Submitted for publication).

The purpose of the present study is to evaluate whether the structure of the peptide moiety of peptidoglycan can also play a role in the stimulation of tumor resistance and whether we can establish a correlation among the different biological activities of a particular peptidoglycan.

MATERIALS AND METHODS

Mice.—Male and female inbred C3H/He, C57BL/6, and (C57BL/6 × C3H/He)F_1 (hereafter called B6C3F_1) mice, 2–6 months old, were obtained from the production colonies of the Institut de Recherches Scientifiques sur le Cancer and maintained in specific-pathogen-free conditions.

Bacterial components.—Peptidoglycans from various gram-positive bacteria were extracted according to the technique of Schleifer and Kandler (*21*) with slight modifications. The bacteria were disrupted by ultrasonic treatment, and the cell walls were collected by differential centrifugation and digested with trypsin (0.5 mg/ml) and ribonuclease (5 µg/ml) in 0.05 *M* phosphate buffer (pH 7.8) at 37°C for 16 hours. The cell-wall digest was then treated with 1% sodium dodecyl sulfate for 10 minutes in a boiling water bath and centrifuged at 12,000×*g* for 30 minutes. After centrifugation, the pellet was washed thoroughly with distilled water. Teichoic acid was extracted with 10% trichloroacetic acid at 4°C for 3 days, and the insoluble residue was washed three times in distilled water and lyophilized. The strains of bacteria that were so treated and the structure of the peptide moiety of their respective peptidoglycans are reported in table 1 (*17*). Soluble peptidoglycan was obtained from *B. megaterium* by treatment with egg-white lysozyme (Sigma

[a] *meso*-Diamino pimelic acid.

Chemical Co., St. Louis, Mo.) as previously described (*22*).

For each preparation, the chemical composition of the peptide moiety was checked by amino acid analysis. The expected ratios of amino acids in the various peptidoglycans were found, and only trace amounts of other amino acids were detected.

C. parvum.—A heat-killed suspension of *C. parvum* (2 mg Pasteur strain 4182/ml) was provided by Prof. R. Ducluzeau (Centre National de la Recherche Zoologique, Jouy-en-Josas, France).

Tumors.—Fibrosarcomas were originally induced in females by 2 mg 3-methylcholanthrene sc and were serially transplanted in syngeneic mice. Tumors from the 5th to 30th passages were used. They were removed aseptically and cut into small pieces. Tumor pieces were suspended in 0.25% trypsin in phosphate-buffered saline and stirred for 90 minutes at 37°C. After passage through sterile gauze, tumor cells were centrifuged and suspended in EMEM, and the number of viable cells was determined by trypan blue exclusion.

Tumor C3-9 was induced in C3H/He mice and tumor B6-2, in C57BL/6 mice; the number of tumor cells that induced 100% tumors in syngeneic mice were, respectively, 3×10^4 and 4×10^4 cells. In all experiments, these doses were used sc or ip in syngeneic and in semiallogeneic mice because no hybrid resistance was observed for these tumors.

In vivo test procedure.—Lyophilized peptidoglycans were suspended in EMEM, sterilized by heat in a boiling water bath, and redispersed by sonication before use. Tumor cells and peptidoglycans, at the desired concentrations, were mixed and immediately injected either sc or ip in a total volume of 0.1 ml. For mice inoculated sc, the tumor size was measured twice a week; for mice inoculated ip, mortality was recorded daily.

Mitogenic activity evaluation.—Mitogens used were PHA (HA 16; Burroughs-Wellcome Ltd., Beckenham, England) (final concentration, 1 µg/ml), LPS extracted from *Escherichia coli* 055:B5 (Difco Laboratories, Detroit, Mich.), and peptidoglycans (several concentrations).

Lymphocytes were cultured from spleens that were aseptically removed, minced with scissors, filtered through a 200-mesh stainless steel sieve, and then washed in EMEM. Single cell suspensions were prepared in RPMI-1640 medium supplemented with 10% complement-inactivated (56°C, 30 min) fetal calf serum (GIBCO, Grand Island, N.Y.), 2 m*M* glutamine (GIBCO), 100 U penicillin/ml, and 100 µg streptomycin/ml. Aliquots of 100 µl containing 2.5×10^5 spleen cells were placed in wells of Falcon #3040 MicroTest plates (Falcon Plastics, Oxnard, Calif.). To each well was added 100 µl of medium containing the mitogen at the desired concentration. All cultures were done in triplicate. The MicroTest plates were incubated at 37°C in a humidified atmosphere of 95% air-5% CO_2 for 24 hours, after which 1 µCi of [^{3}H]dThd (TMM 79 B; CEA, Gif-sur-Yvette, France; [*methyl*-^{3}H]dThd sp act: 25 Ci/m*M*) was added to each well. Cultures were harvested 18 hours later on glass fiber filters with a multiple sample collector (Skatron; Flow Laboratories, Inc., Ayrshire, Scotland). The glass fiber discs were then placed in toluene-based scintillation fluid (Lipoluma; Lumac, Basel, Switzerland), and the radioactivity was counted in an SL 30 Intertechnique scintillation spectrometer. The results are expressed as the mean net counts per minute. (Δ cpm = difference between responses in stimulated and unstimulated cultures; from 2 to 6×10^3 cpm were obtained in unstimulated cultures.) SI was calculated as the mean cpm in experimental culture/mean cpm in unstimulated culture.

Spleen cells were treated with anti-Thy 1.2 serum and complement. Anti-Thy 1.2 serum was prepared by the method of Reif and Allen (*23*). This antiserum killed 95% of thymocytes when it was diluted 1:10 and complement was present. Spleen cells (2.5×10^7 cells) were incubated on ice with 1 ml of diluted anti-Thy 1.2 serum for 60 minutes. The antiserum was then removed, and complement was added as 1 ml of fresh guinea pig serum diluted 1:10. After a further 30-minute incubation at 37°C, the cells were washed and adjusted to the desired concentration, and mitogenic activity was tested.

RESULTS

Local effects in mice administered particulate and soluble peptidoglycans sc.—When C3H/He mice were inoculated sc with peptidoglycan extracted from *B. megaterium* admixed with tumor cells, the peptidoglycan induced a delay in tumor appearance and a decrease in tumor take, as compared with tumor cell-inoculated controls. This effect was dose-dependent in the range of 5–500 µg peptidoglycan/animal (table 2). When injected at the same concentration and tested

under the same conditions, whole heat-killed *C. parvum* was a more efficient antitumor agent than the peptidoglycan extracted from *B. megaterium* (table 2).

The peptidoglycan from *S. aureus* also inhibited tumor growth. The activities of purified peptidoglycan and whole cells were compared. Although peptidoglycan was more active than whole cells, the difference was not statistically significant (text-fig. 1). The effects of both preparations were more pronounced in F_1 mice than in syngeneic mice.

After solubilization by lysozyme treatment, the antitumor activity of peptidoglycan was decreased as compared with that of particulate peptidoglycan (table 2); although a significant decrease in the tumor growth rate was still observed, nearly all animals developed tumors. This indicated that the oligomeric form of peptidoglycan possessed some activity but was less efficient than the particulate and polymerized forms.

Comparative effects of peptidoglycans having different structures.—The local effect on tumor growth was tested after mice were inoculated sc with several peptidoglycans extracted from different bacteria. With C3-9 and B6-2 tumors, we found a reproducible difference between peptidoglycans. Those extracted from *B. megaterium* and *S. aureus* inhibited tumor growth, while peptidoglycans extracted from *Corynebacterium poinsettiae* and *Micrococcus lysodeikticus* were devoid of antitumor effect (text-figs. 2, 3).

Lack of direct cytotoxicity of peptidoglycans on tumor cells.—The addition of peptidoglycan to tumor cell cultures did not decrease their level of [^{3}H]dThd incorporation (table 3). Thus the effect of peptidoglycans on tumor growth cannot

be related to a cytotoxic effect on tumor cells.

Local effects in mice administered peptidoglycans ip.—When C3H/He and B6C3F_1 mice were inoculated ip with admixed peptidoglycans and tumor cells, their MST was never extended and was often shortened. The absence of antitumor activity and occasional tumor enhancement were observed with all of the tested peptidoglycans, including those effective sc and those inactive (table 4). The same observations on tumor growth were made when peptidoglycan was administered in the range of 5–200 μg admixed with tumor cells (table 5). Results obtained when peptidoglycan was injected before tumor cells, at 2-day intervals from 12 to 1 days, have shown an absence of antitumor effect and an occasional tumor enhancement (data not shown).

TABLE 3.—*Lack of direct cytotoxicity of different peptidoglycans on C3-9 tumor cells*[a]

[a] Cytotoxicity was determined after 5×10^3 C3-9 tumor cells/well were incubated 48 hr at 37°C with the indicated concentrations of peptidoglycan. During the last 6 hr, 1 μCi [^{3}H]dThd/well was added. After the radioactive culture medium was removed, the cells were resuspended by trypsin treatment and harvested with a multiple sample collector on glass fiber filters. The incorporated radioactivity was then determined.

[a] Data are mean net counts per min. Each value is the mean of triplicate wells counted in a representative experiment. SI was calculated with respect to controls.

cans (*C. poinsettiae* and *M. lysodeikticus*) have no significant mitogenic activity (table 6).

Peptidoglycans induced a proliferation of B-cells, because the elimination of T-cells by anti-Thy 1.2 serum and complement treatment did not modify the SI (table 7) and spleen cells from nude mice were stimulated by peptidoglycan (table 8). After solubilization of peptidoglycan by lysozyme treatment, the SI was dramatically decreased (table 9).

DISCUSSION

Bacterial extracts exhibiting antitumor activity were generally cell walls or cell wall components (*6–14*). However, some authors have reported that cell walls could be less active than whole cells (*7*, *11*, *15*). With *S. aureus*, the antitumor activities of whole bacteria and peptidoglycan were similar. This demonstrates that the peptidoglycan is an important stimulant for tumor resistance.

The antitumor activity of peptidoglycans extracted from four gram-positive bacteria were compared: Only some peptidoglycans (from *B. megaterium* and *S. aureus*) enhanced

[a] Particulate peptidoglycan was extracted from *B. megaterium*.

[b] Soluble peptidoglycan was obtained from *B. megaterium* peptidoglycan after lysozyme treatment.

tumor rejection when administered sc. The others (from *M. lysodeikticus* and *C. poinsettiae*) possessed no antitumor effects. Identical results were found with two fibrosarcomas, both poorly immunogenic. These two tumors showed no hybrid resistance; thus we checked the action of the different peptidoglycans in hybrid F$_1$ mice under the same conditions as in syngeneic parents. Peptidoglycan from *S. aureus* was even more effective in rejecting tumors in F$_1$ hosts than in the parents; peptidoglycan from *M. lysodeikticus* had no antitumor effect on C3-9 tumor and a weak effect on B6-2 tumor. These results show that the peptidoglycan structure is essential in determining (stimulating) tumor resistance.

As for other immunostimulants, the route of injection is important for the expression of antitumor activity (*10*, *24–26*). When tested ip, all the peptidoglycans were inactive. The absence of an intraperitoneal effect with peptidoglycans could be explained by the following two reasons: first, by the nature of the tumor (*27*) because the tested fibrosarcomas were not ascites tumors but grew in a solid form likely to be insensitive to the intraperitoneal treatment with peptidoglycan. The second reason could be the lack of a lipid component in the cell walls of gram-positive bacteria. It is well established that BCG and *C. parvum* possess an antitumor effect when given ip and that the lipid components of their cell walls seem responsible, at least in part, for their activity (*28*, *29*). Moreover, some lipids can amplify the antitumor activity of mycobacterial cell wall components, chemically defined, such as cord factor (*10*, *14*).

We have shown that ip peptidoglycans either had no effect or had induced tumor enhancement. Enhancement could be observed with all of the tested peptidoglycans, whatever their activity sc. When given ip, the peptidoglycans were in close contact with numerous macrophages. It is known that stimulation of macrophages can induce the release of lysozyme (*30*, *31*), which could rapidly destroy the peptidoglycans, and this might explain the absence of a dose effect when peptidoglycans were given ip. As with other immunostimulants, the mechanism of occasional tumor promotion could be due to the induction of suppressor cells (*32–34*) and to the release of prostaglandins (*35*, *36*), but the reason why these suppressive mechanisms occur only in some instances remains unknown.

Studies with synthetic derivatives of peptidoglycan have established that the structure of the peptide moiety is critical in the expression of adjuvant and mitogenic activities (*37*), and this is especially true for the first two amino acids of the peptide chain (*37–39*). We have shown that the peptidoglycans for which the peptide sequence begins with -LAla-DGlu (as for *B. megaterium*) or -LAla-DGluNH$_2$ (as for *S. aureus*) possess mitogenic and antitumor activities; such peptidoglycans also present adjuvant activity (Guenounou M, Goguel AF, Nauciel C: Submitted for publication). When the first amino acid is a glycine (as for *C. poinsettiae*) or when the α-carboxyl group of D-glutamic acid is linked to a glycyl residue (as for *M. lysodeikticus*), adjuvant and mitogenic activities are not expressed.

Mitogenic and antitumor activities were reduced by lysozyme treatment; this suggests that the polymerization increases the activity of the molecule (*40*) and that these biological effects are not related to the presence of contaminants. Our results and those obtained by Guenounou have shown that some peptidoglycans were mitogenic for B-cells from several strains of mice, unrelated to the LPS response.

These findings raise the problem of whether or not a correlation could exist between adjuvant, B-cell mitogenic, and antitumor activities. A direct role for B-cells in tumor rejection seems rather unlikely, because these tumors were poorly immunogenic and the role of antitumor antibodies in tumor defense is far from proved. But the same structure could be necessary to induce adjuvant activity and B-cell proliferation and to stimulate the cells involved in tumor resistance.

Rat Hepatomas: Chemotherapy With Lycurim and Pyrazofurin[1,2,3]

May S. Lui,[4] Robert C. Jackson,[4] Ronald J. Harkrader,[4] *and* **George Weber[4,5]**

ABSTRACT—Hepatoma 8999 was sensitive to Lycurim [1,4-di-(methylsulfonyloxy-ethylamino)-1,4-dideoxy-*ms*-erythritol] with a mean lethal dose (LD_{50}) of 8.1×10^{-8} *M* for a 6-hour treatment in vitro. The drug dose lethal to 10% of the rats with Lycurim (10 mg/kg) injected ip 12 times into hepatoma 8999-bearing BUF rats at 10-day intervals provided a mean increase in life-span (ILS) of 156%. The more rapidly growing, less differentiated hepatoma 3924A was tenfold less sensitive to Lycurim in vitro, and three treatments in vivo (10 mg/kg given every 8 days) gave an ILS of only 18% in ACI/N rats. Because hepatoma 8999 had a high adenosine kinase activity, the effect of Pyrazofurin (PF; 3-β-D-ribofuranosyl-4-hydroxypyrazole-5-carboxamide) was examined in vitro: The LD_{50} was 8.5×10^{-8} *M* in a 6-hour exposure. In hepatoma 3924A, with a fifteenfold lower adenosine kinase, the LD_{50} was 22-fold higher. Three treatments with PF (4 mg/kg given every 2 days) in hepatoma 8999 caused an 18% ILS and no host toxicity, but in hepatoma 3924A no significant ILS was observed. Lycurim combined with PF (0.05 *μM* each) in hepatoma 8999 cells in vitro provided synergistic kill, but Lycurim and PF (0.3 and 1 *μM*, respectively) in hepatoma 3924A cells yielded summation. When 10 rats with hepatoma 8999 were treated 15 times with the optimal dose of Lycurim (7.5 mg/kg every 10½ days), 1-year survivors numbered 7. Alternate doses of Lycurim (7.5 mg/kg) and PF (3 mg/kg) at 5-day intervals for 4 months to 10 rats gave an ILS of 152% with eight 1-year survivors and no host toxicity.—JNCI 1982; 68:665–668.

Hepatomas in general are extremely refractory to chemotherapy (*1, 2*), and slowly growing hepatomas are usually less responsive to chemotherapy than are rapidly growing hepatomas. This report presents chemotherapy studies with two transplanted rat hepatomas: the rapidly growing, poorly differentiated hepatoma 3924A and the more slowly growing, moderately differentiated hepatoma 8999. The investigation was done with two agents: the antimetabolite PF (3-β-D-ribofuranosyl-4-hydroxypyrazole-5-carboxamide; NSC-143095) and the bifunctional alkylating agent Lycurim [1,4-di-(methylsufonyloxy-ethylamino)-1,4-dideoxy-*ms*-erythritol; NSC-122402].

PF (*3, 4*) inhibits growth of transplantable tumors in mice and rats (*4, 5*). It is converted by the action of adenosine kinase (*6*) to its active form pyrazofurin 5′-monophosphate, an inhibitor of orotidylate decarboxylase (*4*). Previous work in this laboratory suggested that PF could be useful in anticancer combination chemotherapy (*7, 8*). Dix et al. (*6*) reported that after injection of PF into mice and rats, the concentration of PF nucleotides in the liver and kidney was almost an order of magnitude higher than that in any other tissues tested. This result affords the potential for exploitation for chemotherapy in those neoplasms of the kidney and liver that still possess sufficient differentiated function to cause extensive accumulation of the biologically active analog nucleotides.

Lycurim (*9*) has been shown to inhibit several experimental tumor systems (*10, 11*). Clinical trials in Hungary suggested that Lycurim had activity against chronic lymphocytic leukemia and some solid tumors (*12*). Earlier work (*13*) indicated that alkylating agents and antimetabolites may often be used effectively in combination (complementary inhibition).

The purpose of the present study was to determine the effect of Lycurim and PF alone and combined on rat hepatomas in vitro and in vivo. A preliminary account of some of these results was presented in (*14*).

MATERIALS AND METHODS

Tumors and animals.—The neoplasms were solid hepatomas 8999 and 3924A. Hepatoma 8999 is moderately differentiated and has a medium growth rate with a transplant interval of 3.5 months. Hepatoma 3924A is more rapidly growing and poorly differentiated and has a transplant interval of 3–4 weeks. The tumor-bearing rats were obtained from Dr. H. P. Morris, Howard University, Washington, D.C. The properties of these tumors were described in (*15*). Hepatoma 8999 was carried in inbred BUF rats and hepatoma 3924A in inbred ACI/N rats. Animals were kept in separate cages and given water and Purina Laboratory Chow ad libitum.

Transplantation.—Approximately 10^6 cells were transplanted sc into the right flank of male rats weighing 100 g. Chemotherapy was begun 2 days after inoculation for hepatoma 3924A and 3 days after inoculation for hepatoma 8999. Ten or more rats were in each treatment group.

Cell culture.—The hepatoma 3924A and 8999R lines were originated in this laboratory from the solid tumor forms of these hepatomas. Both cell lines were grown in monolayer cultures in McCoy's 5-A medium supplemented with 10% fetal calf serum, 100 U penicillin/ml, and 100 μg streptomycin/ml. Hepatoma 3924A was subcultured twice a week; hepatoma 8999R was subcultured at weekly intervals. The log phase doubling time was 15 hours for hepatoma 3924A and 40 hours for hepatoma 8999R (*16*).

For colony assays, cells were exposed to the drug for 6 hours, and then 500 cells were seeded into fresh medium. Colonies were counted after 7 days (3924A) or 8 days (8999R) as described in (*8*).

Drugs and supplies.—Lycurim was provided by Dr. S.

ABBREVIATIONS USED: ILS=increase in life-span; LD_{50}=mean lethal dose; PF=Pyrazofurin.

Eckhardt, National Oncology Institute, Budapest, Hungary. It was dissolved in distilled water immediately before injection because saline accelerated its rate of decomposition. PF was donated by Eli Lilly & Co., Indianapolis, Ind. It was dissolved in physiologic saline. Tissue culture supplies were purchased from Grand Island Biological Co., Grand Island, N.Y., or from Flow Laboratories, Inc., Rockville, Md.; reagent chemicals were from Sigma Chemical Co., St. Louis, Mo.

RESULTS

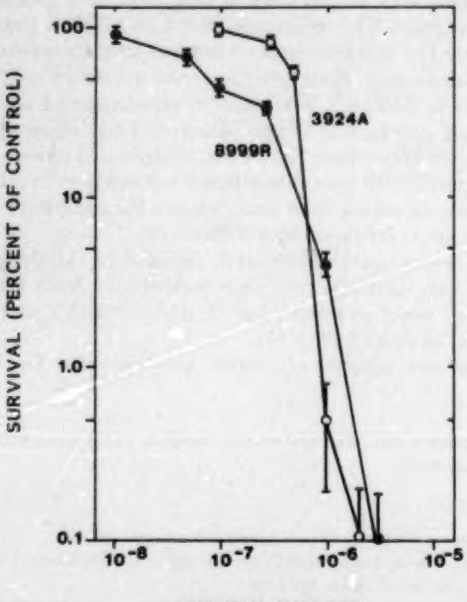
Cytotoxicity of Lycurim and PF as Single Drugs to Hepatoma Cells In Vitro

The survival curve of logarithmically growing cells treated with Lycurim shows that, at low concentrations of the drug, hepatoma 8999R cells were more sensitive than 3924A cells (text-fig. 1). Survival for both cell lines dropped sharply at Lycurim concentrations higher than 3×10^{-7} *M*.

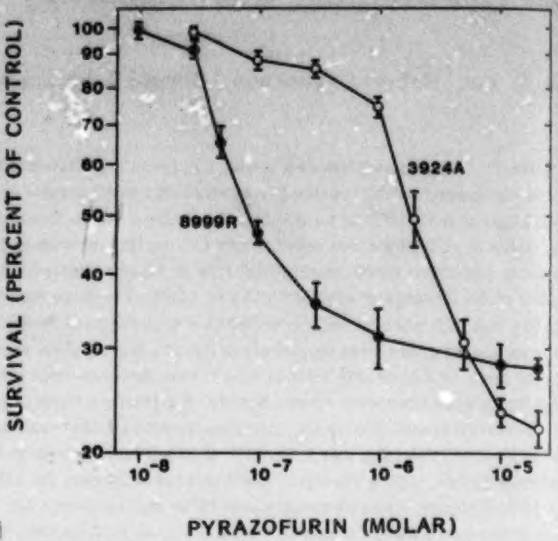
The differential sensitivity of the two cell lines to PF was even more pronounced (text-fig. 2). Survival dropped sharply for hepatoma 8999R cells at PF concentrations higher than 3×10^{-8} *M*, whereas there was still 75% survival for hepatoma 3924A cells at 10^{-6} *M* PF. The LD_{50} values of Lycurim and PF after 6 hours' treatment are summarized in table 1.

Cytotoxicity of Lycurim and PF Combinations to Hepatoma Cells In Vitro

In hepatoma 8999R cells, Lycurim at 5×10^{-8} *M* gave 68% survival and PF at 5×10^{-8} *M* yielded 65% survival. The two agents together resulted in 29% survival when 44% was the value predicted by summation (table 2). Treatment of hepatoma 8999R cells with Lycurim (2×10^{-8} *M*) and PF (3×10^{-8} *M*) also provided synergistic cell kill with a survival of 44%



TEXT-FIGURE 1.—Cytotoxicity of Lycurim to hepatoma cells in vitro (6-hr exposure). A total of 500 treated cells were seeded, and colonies were counted after 7 days (3924A) or 8 days (8999R). *Vertical bars* indicate standard deviation.



TEXT-FIGURE 2.—Cytotoxicity of PF to hepatoma cells in vitro (6-hr exposure). A total of 500 treated cells were seeded, and colonies were counted after 7 days (3924A) or 8 days (8999R). *Vertical bars* indicate standard deviation.

TABLE 1.—*LD_{50} values for 6-hour treatment as measured in colony assay*

Drugs	LD_{50} values for hepatoma cells	
	3924A	8999R
Lycurim	5.2×10^{-7} *M*	8.1×10^{-8} *M*
PF	1.9×10^{-6} *M*	8.5×10^{-8} *M*

TABLE 2.—*Cytotoxicity of Lycurim and PF combinations to hepatoma 8999R cells in vitro (6-hr treatment)*

Drugs (concentrations)	Measured colony count, % control	Predicted for summation[a]
Lycurim (2×10^{-8} *M*)	83	
PF (3×10^{-8} *M*)	92	
Lycurim (2×10^{-8} *M*) + PF (3×10^{-8} *M*)	44	76
Lycurim (5×10^{-8} *M*)	68	
PF (5×10^{-8} *M*)	65	
Lycurim (5×10^{-8} *M*) + PF (5×10^{-8} *M*)	29	44

[a] Assuming summation as defined by Webb (*17*).

By contrast, in hepatoma 3924A cells, the combinations of Lycurim and PF were only summative (table 3).

Chemotherapy of Hepatoma 8999 In Vivo

Table 4 compares the treatment of hepatoma 8999-bearing rats with different dosage levels of Lycurim and PF.

TABLE 4.—*Chemotherapy of hepatoma 8999 in vivo*

Treatment and dose regimen[a]	No. of toxic deaths/total No. of rats treated	ILS,[b] %	No. of 1-yr survivors/total No. of rats treated
Lycurim (15 mg/kg) given every 10 days (8 treatments)	8/10	38	1/10
Lycurim (12.5 mg/kg) given every 10 days (8 treatments)	8/10	125	0/10
Lycurim (10 mg/kg) given every 10½ days (15 treatments)	1/10	156	2/10
Lycurim (7.5 mg/kg) given every 10½ days (15 treatments)	0/10	164	7/10
Lycurim (10 mg/kg), single dose	2/10	38	0/10
PF (4 mg/kg) given every 2 days (3 treatments)	0/10	18	0/10
PF (6 mg/kg) given every 10 days (12 treatments)	1/10	17	0/10
Lycurim (7.5 mg/kg)+PF (3 mg/kg), single dose	2/10	30	0/10
Lycurim (7.5 mg/kg)+PF (3 mg/kg) given every 10½ days (15 treatments)	4/10	159	1/10
Lycurim (7.5 mg/kg)+PF[c] (3 mg/kg) given every 10½ days (15 treatments)	0/10	152	8/10

[a] Tumors were implanted at the same time, and rats were randomized between the groups. Treatment commenced 3 days after inoculation. Drugs were administered ip.

[b] Life-span of control rats was 124±18 days (mean ± SD for 30 rats). For calculation of ILS, 1-year survivors were counted as 365 days.

[c] PF doses were given 5 days after Lycurim.

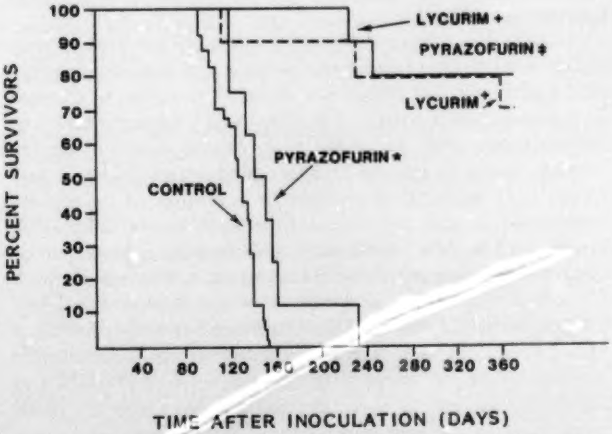
Eight treatments with Lycurim at 15 mg/kg every 10 days or at 12.5 mg/kg every 10 days were very toxic to hepatoma 8999-bearing rats. Only 2 of 10 rats survived in each group with an ILS of 38 and 125%, respectively. Lycurim at 10 mg/kg was much less toxic. A single dose of Lycurim (10 mg/kg) yielded only a 38% ILS, whereas a similar dosage given every 10½ days (15 treatments) resulted in a 156% ILS with two 1-year survivors. The same schedule of Lycurim at 7.5 mg/kg produced no toxic death and increased the ILS to 164%, and there were seven 1-year survivors of 10 rats treated. Three treatments with PF at 4 mg/kg given every 2 days resulted in an 18% ILS in hepatoma 8999-bearing rats. Increasing the dose to 6 mg/kg given every 10 days (12 treatments) led to one toxic death with no increase in ILS. PF by itself resulted in no 1-year survivors.

Although neither Lycurim (7.5 mg/kg) nor PF (4 mg/kg) caused any toxic deaths when given alone, the combination was toxic in hepatoma 8999-bearing rats. Therefore, the dose of PF administered in combination with Lycurim was lowered to 3 mg/kg. A single dose of Lycurim (7.5 mg/kg) plus PF (3 mg/kg) yielded two toxic deaths among 10 rats treated. The ILS of 30% was observed with no long-term survivors. The same combination when given every 10½ days (15 treatments) was more effective with a 159% ILS and one 1-year survivor, although it increased the toxicity to the rats. The same dose when injected sequentially (PF given 5 days after Lycurim) did not further increase the ILS, but there were eight 1-year survivors among 10 rats treated. This schedule also reduced the toxicity of these drugs. Some of these data are presented in text-figure 3.

Chemotherapy of Hepatoma 3924A In Vivo

Lycurim at 10 mg/kg and 7.5 mg/kg yielded one toxic death among 10 rats treated. PF at 8 mg/kg also led to one toxic death. The two agents together were much more toxic than when they were used alone. Lycurim at 10 mg/kg with either 6 or 8 mg/kg PF was very toxic in ACI/N rats; among 10 rats in each group, there were five and seven toxic deaths, respectively. Lowering the dose of Lycurim in these combinations to 7.5 mg/kg reduced the number of toxic deaths to 1 and 2 rats, respectively.

Table 5 compares the treatment of hepatoma 3924A-bearing rats with different dosage levels and schedules of Lycurim and PF. Lycurim was less toxic in hepatoma 3924A-bearing rats than in hepatoma 8999-bearing rats. However, it was also less effective, resulting in only a 16–18% ILS. PF by itself was more toxic in tumor-bearing rats than in normal rats. Three treatments with PF at 6 mg/kg given every 2 days resulted in five toxic deaths and a 29% ILS. A single dose of Lycurim (10 mg/kg) and PF (4 mg/kg) resulted in three toxic deaths with a 12% ILS. A second treatment at the same dosage failed to improve survival among these rats.



TEXT-FIGURE 3.—Chemotherapy of hepatoma 8999 in vivo. *=PF (4 mg/kg) given every 2 days (3 treatments). †=Lycurim (7.5 mg/kg) given every 10½ days (15 treatments). ‡=Lycurim (7.5 mg/kg)+PF given every 10½ days (16 treatments), with PF injected 5 days after Lycurim.

TABLE 5.—*Chemotherapy of hepatoma 3924A in vivo*

Treatment and dose regimen[a]	No. of toxic deaths/ total No. of rats treated	ILS,[b] %
Lycurim (10 mg/kg) given every 8 days (2 treatments)	0/10	18
Lycurim (15 mg/kg) given every 8 days (2 treatments)	1/10	16
Lycurim (20 mg/kg) given every 10 days (2 treatments)	7/10	13
PF (6 mg/kg) given every 2 days (3 treatments)	5/10	29
Lycurim (10 mg/kg)+PF (4 mg/kg) given every 10 days (2 treatments)	3/10	3
Lycurim (10 mg/kg)+PF (4 mg/kg), single dose	3/10	12

[a] Tumors were implanted at the same time, and rats were randomized between the groups. Treatment commenced 1 day after inoculation. Drugs were administered ip.

[b] Life-span of control rats was 36±4 days (mean ± SD) for 30 rats.

DISCUSSION

Because many of the enzymatic properties of hepatoma 8999 closely resemble those of moderately differentiated human hepatocellular carcinomas (*18*), we believe that this experimental system may provide a useful model for developing chemotherapy against the human disease. Lycurim, which in the optimal protocol gave 7 long-term survivors among 10 rats treated (when treatment was commenced 3 days following implantation), is the most effective single agent found so far for treatment of hepatoma 8999. Although rapidly growing tumors are frequently more responsive to alkylating agents than are more slowly growing neoplasms, hepatoma 3924A was less sensitive to Lycurim both in vitro and in vivo than was hepatoma 8999. The reason for this anomaly is not known.

Hepatoma 3924A was also much less sensitive in vitro to PF than was hepatoma 8999. This difference was probably a consequence of the higher adenosine kinase activity of hepatoma 8999 (*19*).

An effective strategy in combination chemotherapy is to utilize a cell cycle-phase-specific agent with a phase-nonspecific agent. For this reason we studied the action of PF and Lycurim in combination. The effect of an antimetabolite in combination with an agent that causes macromolecular damage has been termed "complementary inhibition." Sartorelli (*13*) reported a number of examples of synergistic interaction in vivo between antimetabolites and alkylating agents, and Schabel and Laster (*20*) described the potentiation of alkylating agents by 6-thioguanine. Our results with PF and Lycurim are unusual, however, in that synergism was obtained in vitro. This combination will provide a valuable model system for the study of the biochemical mechanism of the interaction between antimetabolites and alkylating agents. In vivo, the combination appears to be more toxic to the host animal than either agent used separately (tables 4, 5). This toxicity could be decreased by the administration of PF 5 days after Lycurim, and this combination gave a slightly better result than the best regimen of Lycurim alone. The 1-year survivors were tumor-free and appear to represent "cures." It is likely that this protocol is not yet optimal, and in future work we shall study the schedule dependence in greater detail. Important questions to be answered are to what extent may PF be replaced by other antimetabolites and Lycurim by other alkylating agents.

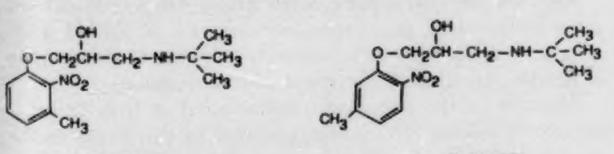
Liver Tumors Induced by a New Beta-Adrenoreceptor Blocking Agent in Female Rats[1,2,3]

Giovanni Ragnotti,[4] Marco Presta,[4] Laura Riboni,[4] *and* Teresa Zavanella[5,6]

ABSTRACT—A newly synthesized beta-adrenoreceptor blocking agent, DL-1-(2-nitro-3-methyl-phenoxy)-3-*tert*-butylamino-propan-2-ol (ZAMI 1305), administered intragastrically for 6 months induced hepatocellular carcinomas in female outbred Wistar rats in a dose-dependent fashion but was harmless to the livers of male outbred Wistar rats. Experiments with castrated animals confirmed the dependence of the carcinogenic effect of ZAMI 1305 on the hormonal status of the rat. When an isomer of ZAMI 1305, DL-1-(2-nitro-5-methyl-phenoxy)-3-*tert*-butylamino-propan-2-ol (ZAMI 1327), and DL-practolol, which have pharmacologic activities similar to those of ZAMI 1305, were administered by the same experimental technique as used for ZAMI 1305, no liver tumors appeared either in male or female rats.—JNCI 1982; 68: 669–672.

Tumor-promoting (*1*) or oncogenic (*2*, *3*) activities of some beta-adrenoreceptor blocking agents have been reported. The suggestion that the oncogenic activity of these agents is related to their pharmacologic properties rather than to other mechanisms (*4*) is very disturbing from a clinical point of view. This suggestion seems to go along with the facts that those beta-blocking agents suspected to be oncogenic have rather different chemical structures and that a well-known hepatocarcinogen, 2-acetylaminofluorene (*5*), has been shown to have a beta-adrenoreceptor blocking activity (*6*).

Therefore, we investigated two newly synthesized molecules, ZAMI 1305 and ZAMI 1327, which have a comparable beta-adrenoreceptor blocking activity (*7*) and differ very slightly in their chemical structure (text-fig. 1), in their capacity to induce neoplastic transformation. Practolol, for which there are some indications of tumorigenicity in rodents (*3*), was included in the experiment for comparison.



ZAMI 1305 ZAMI 1327

TEXT-FIGURE 1.—Chemical structure of ZAMI 1305 and ZAMI 1327.

MATERIALS AND METHODS

In a first experiment, outbred Wistar rats, 160 females and 160 males (Nossan, Correzzana, Italy) weighing 60–70 g each, were used. They were maintained on a complete standard diet of laboratory chow (Nossan) and water ad libitum. Constant temperature (22–24°C) and alternating periods of 12-hour dark and 12-hour light were also maintained. The animals were distributed at random into 8 groups for each sex (20 animals/group). One group was kept as a control, 1 group was treated with DL-practolol (300 mg/kg body wt/day), and the others were treated with ZAMI 1305 or ZAMI 1327 (25, 50, or 100 mg/kg body wt/day) for 6 months. ZAMI 1305, ZAMI 1327 (99.9% purity), and DL-practolol were gifts from Zambeletti S.p.A., Baranzate, Italy. The drugs, dissolved in 1% carboxymethylcellulose, were administered intragastrically (1 ml/100 g body wt). Control rats received the same volume of 1% carboxymethylcellulose. At the end of the treatment, surviving animals were bled to death and autopsied. Liver, lungs, and spleen were fixed in 12% neutral Formalin, and paraffin sections were stained with H & E.

In a second experiment, ZAMI 1305 was administered intragastrically at a dose of 100 mg/kg body weight/day to 16 castrated male rats treated im with 1 μg 17β-estradiol/day and 1 mg progesterone/day and to 14 ovariectomized female rats treated im with 100 μg testosterone/day. Hormone treatment was initiated immediately after surgery and continued throughout the experimental period. ZAMI 1305 administration was initiated 1 week after surgery. Controls were 11 male and 11 female intact rats treated with the same amount of ZAMI 1305. Some of the animals died or were killed after 2–5 weeks. The remaining animals were killed after 12 weeks. The animals were autopsied, livers were fixed in 12% Formalin, and paraffin sections were stained with H & E.

Liver lesions were histologically typed according to the classification of rat liver lesions suggested by the National Academy of Sciences (*8*).

RESULTS

Intact Animals

During the first month of treatment, 3–6 female rats treated with different doses of ZAMI 1305 (table 1) died with signs of hepatic failure. No other females died subsequently. No mortality was observed in male rats treated with ZAMI 1305 and in male and female rats treated with ZAMI 1327 and DL-practolol.

TABLE 1.—*Liver tumor prevalence in female rats treated with ZAMI 1305 for 6 months*

ZAMI 1305, mg/kg body wt/day	No. of surviving animals[a]	Relative liver wt, g/100 g body wt, mean ± SEM	No. of animals with: Neoplastic nodules (%)	Hepatocellular carcinoma (%)	Lung metastases
0	17	2.4 ± 0.1	0	0	0
25	17	3.5 ± 0.1[b]	7 (41)	1 (6)	0
50	18	4.3 ± 0.2[b]	13 (72)	5 (28)	0
100	14	6.5 ± 0.9[b]	12 (86)	9 (64)	4[c]

[a] No. of animals at start of experiment, 20. Rats that died during the experiment were excluded.

[b] Treated rats statistically different vs. the controls ($P<0.01$) as assessed by analysis of variance.

[c] Peritoneal spread was also present in 1 animal.

After 6 months, dose-related gross liver changes were present in female rats treated with ZAMI 1305. The liver was increased in weight (table 1) and there were whitish nodules of varying sizes (1–5 mm in diameter) at the capsular and cut surface, with hemorrhagic and cystic areas. Histologically, poorly differentiated to well-differentiated hepatocellular carcinomas (fig. 1), sometimes with areas with adenomatous patterns, were found in dose-dependent numbers (table 1). Lung metastases (figs. 2, 3) were present in 4 animals, and 1 animal also had peritoneal spread. Marked splenic enlargement, due to the presence of extensive foci of hematopoiesis, was observed in these females with large, metastatic tumors.

No liver changes were detected on gross and histologic examination in male rats given ZAMI 1305, in rats of either sex treated with ZAMI 1327 and DL-practolol, or in the controls.

Castrated Animals

To substantiate the role of the hormonal environment in liver carcinogenesis by ZAMI 1305, we administered the drug for a maximum of 3 months to 17β-estradiol–progesterone-treated castrated male rats and to testosterone-treated ovariectomized female rats. Histologic modifications of the livers of these animals were compared to those observed in male and female intact rats given the same dose of ZAMI 1305.

The temporal sequence of early pathologic changes in the livers of castrated male and intact female rats mirrored that generally found after treatment with hepatic carcinogens (*8*). After 2–5 weeks of treatment, oval cell hyperplasia, tubular arrangement of the hepatocytes, and foci of acidophilic cells and of clear cells were found. After 3 months, neoplastic nodules (fig. 4) were present in most of the animals (table 2). In ovariectomized female and in intact male rats, small foci of clear cells or basophilic cells were occasionally detected.

TABLE 2.—*Liver lesions in castrated male rats and ovariectomized female rats treated with ZAMI 1305[a] for 3 months*

Sex	Castrated or ovariectomized[b]	No. of animals	Oval cell hyperplasia	Clear cell foci	Neoplastic nodules
Male	No	5	0	1	0
Male	Yes	3	3	1	2
Female	No	3	3	2	3
Female	Yes	5	0	1	0

[a] All the animals were treated with 100 mg ZAMI 1305/kg body wt/day.

[b] Castrated males were treated im with 1 μg 17β-estradiol/day and 1 mg progesterone/day. Ovariectomized females were treated im with 100 μg testosterone/day.

DISCUSSION

Our results demonstrate that ZAMI 1305, a newly synthesized beta-adrenoreceptor blocking agent (*7*), when administered daily for 6 months, induces hepatocellular carcinomas in female outbred Wistar rats in a dose-dependent fashion but is ineffective in male outbred Wistar rats.

Other chemical carcinogens have been shown to have different oncogenic capacities in male and female rats (*9*). This difference has been ascribed either to a different metabolism of the molecules (*10, 11*) in the two sexes or to the sex-hormone status (*12, 13*). As for ZAMI 1305, its different oncogenic capacity in the two sexes does not seem to be related to a different metabolism of the molecule. We have in fact found (Presta M, Riboni L, Aletti MG: Unpublished data) that within month 1 of treatment the same metabolites of ZAMI 1305 (2-nitro-3-methyl-phenoxy-propan-1,2-diol, 2-nitro-3-methyl-phenoxy-ethyl-amino-propan-2-ol, and 2-amino-3-methyl-phenoxy-*tert*-butylamino-propan-2-ol) are found in the urine of rats of both sexes. However, Passetti et al. (*14*) reported an incapacity of female rats to metabolize ZAMI 1305 after a 6-month treatment, which could be due to a reduced capacity of the female neoplastic liver to metabolize this substance. An impaired capacity of hepatomas to metabolize foreign chemicals has in fact been reported (*15*).

Also, the *Salmonella*/microsome test of Ames (*16*) did not show evidence of any mutagenic activity of ZAMI 1305 after activation with microsomes from livers of either male or female rats (Sora S: Personal communication).

The role of the hormonal environment in liver carcinogenesis by ZAMI 1305 is substantiated by the results of the experiments with hormone-treated castrated animals. Surgery and hormone treatment in fact completely reverse the response to ZAMI 1305. After 3 months of treatment, neoplastic nodules were present in the livers of both intact female and 17β-estradiol–progesterone-treated castrated male rats, whereas only minor histologic alterations were observed in the livers of male and testosterone-treated ovariectomized female rats. Although we cannot exclude the possibility that a longer period of treatment or a different experimental scheme from the one adopted in this work could result in oncogenicity for ZAMI 1305 also in male rats, the data presented strongly suggest that the oncogenic effectiveness of ZAMI 1305 is related to the sex-hormone status of the animal.

No liver lesions were observed either in female or male rats after a 6-month treatment with DL-practolol and ZAMI 1327, an isomer of ZAMI 1305. However, in 2 of 5 female rats given ZAMI 1327 at a higher dose (400 mg/kg body wt/day) very small foci of basophilic cells were occasionally detected (Zavanella T: Unpublished observations).

As for the more general problem of the carcinogenic risk of beta-adrenoreceptor blocking agents, although our data failed to show evidence of tumor growth after administration of ZAMI 1327 and DL-practolol, the results obtained with ZAMI 1305 seem to indicate that, in agreement with previous reports (*3*, *4*), this class of substances must be considered potentially oncogenic, at least under some defined conditions.

The study of the mechanism(s) underlying the observed different oncogenic capacities of ZAMI 1305 and ZAMI 1327, molecules having a similar pharmacologic activity (*7*) and differing very slightly in their chemical structures, should be elucidating if the suggested oncogenicity of beta-blockers is related to some specific characteristics of their chemical structures or to their pharmacologic activities.

Mechanisms of Immunologic Eradication of a Syngeneic Guinea Pig Tumor. I. Quantitative Analysis of Adoptive Immunity[1,2]

Suyu Shu,[3,4] James T. Hunter,[3] Herbert J. Rapp,[3,5] *and* Leila S. Fonseca[3,6]

ABSTRACT—Adoptive immunity against a syngeneic hepatoma (line-10) of Sewall-Wright inbred strain 2 guinea pigs was analyzed by a two-dimensional titration of iv transferred immune lymphoid cells versus intradermal tumor challenges. Tumor resistance increased exponentially as a function of the number of immune lymphoid cells transferred. Within the tumor challenge doses analyzed, suppression of tumor growth mediated by the transferred immune lymphoid cells appeared to be independent of the primary immune response in the recipient. Quantitatively, rejection of a given number of tumor cells reflected the number of transferred immune cells and was independent of the presence of the same tumor at other skin sites. There was no evidence indicating that transferred immune cells were attracted specifically to the tumor inoculation site. The number of tumor cells that could be rejected at a skin site by adoptive immunity was greater than the estimated number of immune lymphoid cells present at the challenge site.—JNCI 1982; 68:673–680.

The adoptive transfer of specifically sensitized lymphoid cells is a potential means of specific cancer immunotherapy. Transfer to naive syngeneic animals of genetically compatible lymphoid cells specifically sensitized to tumor rejection antigens has prevented the growth of inoculated tumors, caused regression of established local tumors, and eradicated metastases (*1–4*). The requirement for syngeneic or autologous cells for adoptive immunity has limited the applicability of this approach in the treatment of humans with cancer (*5*). The recent development of in vitro methods that permit replication of T-lymphocytes (*6, 7*) that retain immunologic reactivity (*8–11*) has led to renewed interest in the use of adoptive immunity for cancer treatment.

Although previous studies have established its therapeutic efficacy, the mechanism of adoptive immunity against tumors remains an enigma. Direct killing of malignant cells by transferred immune lymphocytes has been postulated and generally accepted as an in vivo mechanism of tumor eradication since several types of neoplastic cells are lysed upon contact with immune lymphoid cells in vitro (*12–15*). In a previous study (*16*), we demonstrated that two major components of cell-mediated tumor immunity, in vitro cytotoxicity and adoptive immunity, reflected separate activities of two different lymphoid cell subpopulations. Two functionally distinct tumor-immune T-cell subpopulations were also identified in a rat Moloney sarcoma system (*17*). A subset of splenic T-cells associated with the elimination of the sarcoma in vivo was poorly tumor-cytotoxic in vitro, whereas the highly tumor-cytotoxic T-cell subset was tumor enhancing in vivo. In view of these findings, we have chosen adoptive transfer rather than an in vitro tumor cytotoxicity assay of undefined in vivo relevancy for mechanistic studies of tumor immunity. We now present the results of a study to elucidate some aspects of cellular mechanisms of adoptive immunity to the syngeneic line-10 hepatoma in strain 2 guinea pigs. This study was undertaken to analyze quantitatively the suppression of id implanted tumors in animals that were adoptively transferred iv with spleen cells from donors specifically immunized to the line-10 hepatoma.

MATERIALS AND METHODS

Guinea pigs.—Male Sewall-Wright inbred strain 2 guinea pigs 3–6 months old were obtained from the Small Animal Section, Veterinary Resources Branch, Division of Research Services, NIH, Bethesda, Md., and from the Division of Cancer Biology and Diagnosis Animal Holding Facility, NCI-Frederick Cancer Research Facility, Frederick, Md. Caged in groups of 6 or fewer, the animals were fed NIH guinea pig ration and given water ad libitum.

Tumor lines.—The line-10 hepatocellular carcinoma was originally induced in a male strain 2 guinea pig by feeding DENA in water. The tumor was converted to the ascites form and was passed ip in weanling strain 2 guinea pigs (*18, 19*). Inoculation of 10^6 viable ascites line-10 cells id in the side of the guinea pig led to progressive tumor growth, regional axillary lymph node metastases, and death in 60–90 days (*20*). At autopsy, a significant proportion of animals was found to have lung metastases (*21*). Another syngeneic DENA-induced hepatocellular carcinoma, line-1, was used for specificity control. Inoculation of 3×10^6 viable ascites line-1 cells id led to tumor growth for approximately 14 days which was followed by spontaneous regression (*18*). The line-10 and line-1 tumors each contained at least one distinct tumor-specific rejection antigen; both shared one or more embryonic antigens (*22, 23*). The ip passaged tumor lines were initiated periodically with ascites tumor cells stored in liquid nitrogen. The line-10 and line-1 tumor cells

used in experiments were in transplantation generations 12–20 and 90–100, respectively.

Immunization with line-10 or line-1 tumors.—Line-10-immune guinea pigs were produced by id inoculation into each animal of 0.2 ml of a vaccine consisting of 10^6 ascites line-10 cells admixed with 212 μg of cell walls from *Mycobacterium bovis* strain BCG (Phipps strain; Trudeau Institute, Saranac Lake, N.Y.) prepared as an emulsion with 3% mineral oil and 0.2% Tween in saline (*24, 25*). After 3–4 weeks, the animals received a series of 3–9 id weekly booster injections of 10^6 ascites line-10 cells in 0.1 ml of medium 199. Line-1-immune animals were produced by an initial id inoculation of 3×10^6 ascites line-1 cells. After a 4-week interval, the animals received 3–4 id booster injections of 3×10^6 ascites line-1 cells in a period of 6–8 weeks. Immune spleens were obtained from animals within 7–14 days after the last booster inoculations.

Preparation of nucleated spleen cell suspensions.—Guinea pigs were killed by cervical dislocation, and their spleens were removed aseptically. The organs were rinsed in RPMI-1640 medium and minced with scissors into pieces 1–4 mm in diameter. The minced tissue was forced through a 60-mesh stainless-steel wire screen and suspended in RPMI-1640 medium. The cell suspension was allowed to settle for approximately 1 minute, and three-fourths of the supernatant was decanted into a centrifuge tube. The remaining cell suspension containing cell aggregates and tissue debris was forced through a 22-gauge needle and was collected as described above. After centrifugation, erythrocytes were lysed by resuspension of the cell pellet in ammonium chloride–potassium lysing buffer (8.290 g NH_4Cl, 1.0 g $KHCO_3$, and 0.0372 g EDTA/liter, pH 7.4; Media Production Section, NIH, Bethesda, Md.). The cells were washed and resuspended in RPMI–FBS. The spleen cell suspension was depleted of plastic-adherent cells by incubation for 24 hours in plastic tissue culture dishes (#3025; Falcon Plastics, Oxnard, Calif.) in a 37°C humidified atmosphere consisting of 5% CO_2 in air.

Cell separation by Percoll gradient.—Percoll, a colloidal silica coated with povidone, was purchased from Pharmacia Chemicals, Uppsala, Sweden. Discontinous gradients were prepared by a modification of previously described methods (*26, 27*). A gradient was formed in a 12-ml plastic tube (#3033; Falcon Plastics) by layering 4 ml of the 35% Percoll solution on 3 ml of 50% Percoll. Approximately 200×10^6 viable spleen cells suspended in 2 ml of RPMI–FBS were layered over the gradient. The gradient was spun at 1,600 rpm ($400\times g$) in an International model PR-2 centrifuge for 30 minutes at room temperature. Cells were carefully removed from the gradient with a pipette and were washed three times with RPMI-1640 medium. Cells recovered in the interface between the 50 and 35% Percoll layers and above the 35% Percoll layer were designated as fractions I and II, respectively.

Adoptive transfer of immunity with spleen cells.—Spleen cells suspended in 2.0 ml of RPMI-1640 medium were transferred iv through the penile vein into normal strain 2 male guinea pigs anesthetized by inhalation of methoxyflurane (Metofane; Pitman-Moore, Inc., Washington Crossing, N.J.). Immediately thereafter, each animal was challenged id on the left side with ascites tumor cells in 0.1 ml medium 199. Challenged animals were observed for 4–6 weeks for evidence of progressive dermal tumor growth. To determine the quantitative relationship between the immune spleen cells transferred and the doses of tumor challenge that could be suppressed, we tested graded doses of immune spleen cells against graded doses of tumor cells. The ED_{50} of immune spleen cells for a given tumor dose and the TD_{50} of line-10 cells for a given immune spleen cell dose were computed by the Reed-Muench formula (*28*), and the standard error of each ED_{50} or TD_{50} was calculated by Pizzi's formula (*29*). Since the tumor challenge is an integral part of the adoptive transfer, we investigated its possible role in amplifying transferred immunity and/or stimulating host tumor immunity by giving a second id tumor challenge to those guinea pigs that had suppressed the growth of the first tumor challenges. The growth or lack of growth of the second challenge provided a means to evaluate quantitatively the immunogenicity of the first tumor challenge.

To estimate the proportion of iv transferred immune cells that accumulate and participate in specific tumor suppression at the site of challenge, we compared the number of immune cells transferred systemically and locally in the suppression of a given dose of tumor challenge. In the local adoptive transfer, tumor cells mixed with spleen cells at various ratios were suspended in RPMI-1640 medium. Immediately thereafter, 0.1 ml of the cell mixture was injected id into a normal guinea pig.

Irradiation of line-10 cells.—Line-10 cells were irradiated at a dose of 20,000 rad with a ^{60}Co γ-ray source (Gammacell 220). After irradiation, the viability of the cells was determined by trypan blue exclusion; no decrease in viability was observed after irradiation. To test whether irradiated cells were capable of growing progressively in strain 2 guinea pigs, we inoculated ip each weanling animal with 20×10^6 irradiated cells. No ascites tumors developed in the inoculated animals. A single, viable line-10 cell is capable of initiating fatal ascites tumor growth (Hunter JT: Unpublished data).

Analysis of results.—Log TD_{50} and log ED_{50} were calculated for tumor inoculation doses and transferred immune spleen cells, respectively, and were evaluated by regression analysis with a programmed calculator (HP-97; Hewlett-Packard Co., Corvallis, Oreg.). Significance of differences between the TD_{50} or the ED_{50} was estimated by Student's *t*-test.

RESULTS

Specificity of Adoptive Immunity

By active immunization, line-10 tumor has been shown to possess at least one tumor-specific rejection antigen distinct from that of other DENA-induced guinea pig hepatomas (*30*). Tumor-specific immunity to line-10 could be also transferred passively to normal recipients by intracardiac injection of mineral oil-induced immune peritoneal exudate cells (*1*). Although BCG cell wall was incorporated for initial immunization of guinea pigs to line-10, there was no evidence of tumor resistance in BCG-sensitized animals by either direct tumor challenge or adoptive transfer. Therefore, in this investigation we studied the specificity of adoptive immunity mediated by spleen cells from animals that had been immunized to the line-10 or the line-1 hepatoma. Table 1 summarizes the results of two experiments demonstrating that immune spleen cells transferred iv were capable of mediating specific suppression of the growth of id tumor challenges. The adoptive immunity against line-10 and line-1 was tumor line-specific; the growth of line-10 tumor was inhibited in animals given line-10 but not in those given line-1-immune spleen cells, whereas the growth of line-1 tumor was inhibited in animals given line-1 but not in those given line-10-immune spleen cells.

Quantitation of Adoptive Immunity by a Two-Dimensional Titration

Transferring 200×10^6 immune spleen cells iv consistently suppressed the growth of 10^6 line-10 tumor cells given id. The quantitative relationship between the number of tumor cells that can be suppressed by a given number of immune spleen cells was established for line-10 by a two-dimensional titration in which the numbers of immune cells and line-10 tumor cells were varied. Over a large range of line-10 challenge doses (10^4–10^7 cells) tested, we found that the efficacy of the adoptive immunity increased with increasing numbers of transferred immune cells (table 2). The data in table 2 were based on determination of complete tumor suppression. In subsequent analyses, quantitative tumor resistance was estimated by comparison of the 50% end points.

TABLE 1.—*Specificity of adoptive transfer of immunity to guinea pig hepatomas*

Source of spleen cells[a]	Tumor incidence[b] in animals challenged with:	
	Line-10	Line-1[c]
Medium control	12/12	6/6
Normal animals	12/12	12/12
Line-10-immune animals	0/12	11/11
Line-1-immune animals	6/6	1/12

[a] Each guinea pig was given 200×10^6 spleen cells iv in 4 ml medium 199 and was challenged id on the same day with 10^6 ascites line-10 or 3×10^6 ascites line-1 cells.

[b] No. of animals with tumor/No. tested 48 days after tumor challenge. Data were pooled from two experiments.

[c] Line-1 tumor normally grew id in medium control animals for ≈14 days before it spontaneously regressed. Immunity to line-1 was evaluated by the observation of a total lack of tumor growth.

TABLE 2.—*Quantitative analysis of adoptive transfer of tumor immunity in guinea pigs by a two-dimensional titration*[a]

No. of immune spleen cells transferred $\times10^{-6}$	Tumor incidence[b] after line-10 challenge dose of:				
	10^3	10^4	10^5	10^6	10^7
0	2/6	10/11	12/12	12/12	12/12
12.5		6/6			
25		1/10	9/11		
50		2/12	4/12	11/12	6/6
100		0/11	0/12	2/12	12/12
200				0/12	10/11
400					0/6

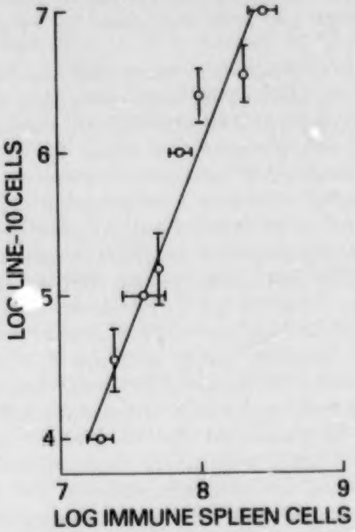
[a] Each guinea pig was given a suspension of immune spleen cells iv in 2 ml of RPMI-1640 medium and was challenged id on the same day with various numbers of ascites line-10 cells in 0.1 ml of medium 199.

[b] No. of animals with tumor/No. tested 38 days after challenge. Data were pooled from two independent experiments.

TABLE 3.—*Relationships between transferred immune spleen cells and line-10 tumor challenge doses in producing 50% end points*[a]

Part	Immune spleen cells $\times10^{-6}$	Log immune spleen cells (SE)	Line-10 dose	Log line-10 dose (SE)
I, TD_{50}	0		2.19×10^3	3.34 (0.27)
	25	7.40	3.55×10^4	4.55 (0.22)
	50	7.70	1.55×10^5	5.19 (0.25)
	100	8.00	2.50×10^6	6.40 (0.20)
	200	8.30	3.55×10^6	6.55 (0.19)
II, ED_{50}	19	7.28 (0.07)	10^4	4.00
	39	7.59 (0.07)	10^5	5.00
	72	7.86 (0.06)	10^6	6.00
	272	8.44 (0.09)	10^7	7.00

[a] TD_{50} and ED_{50} were calculated from data presented in table 2 according to the Reed-Muench formula. The TD_{50} in part I were calculated with fixed numbers of immune spleen cells, and the ED_{50} in part II, with fixed line-10 challenge doses.



TEXT-FIGURE 1.—Logarithmic relationship between immune spleen cells and line-10 tumor challenge doses in producing 50% end points of tumor suppression in syngeneic recipients.

A summary of ED_{50} and TD_{50} determinations is shown in table 3. The 50% end points were computed from two directions: In part I, they were calculated as TD_{50}—numbers of tumor cells that would produce dermal tumors in 50% of animals receiving a given number of immune cells. In part II, they were calculated as ED_{50}—numbers of immune cells required to suppress the growth of a given tumor dose in 50% of the test animals. These values were then plotted logarithmically and analyzed by linear regression (text-fig. 1) The relationship can be illustrated by the linear first-order equation

$$y = 2.51x - 14.07.$$

In this equation, y is log tumor challenge dose, x is log immune cells, and the coefficient of determination of the regression line (r^2) is 0.95. The slope of the equation, 2.51, indicates that the efficacy of tumor suppression by adoptive immunity is an exponential function of increasing numbers of immune cells; i.e., a twofold increment in immune cells leads to an increased resistance of 5.62-fold in the tumor challenge dose.

Role of Host Systemic Immunity in the Rejection of Tumor by Adoptive Immunity

In adoptive transfer experiments, besides being an indicator for specificity and sensitivity of the test, tumor challenge might provide additional antigenic stimulation to the recipient. Therefore, tumor suppression might result from a combined effect of transferred immunity and host immune response. To study the role of host immunity in the rejection of tumor under the conditions of our system, we tested the tumor rejection capacity of guinea pigs in which a previous tumor challenge had been eliminated by adoptive immunity.

Guinea pigs that had been inoculated with various numbers of immune spleen cells were challenged on the same day with various doses of line-10 cells. Animals made tumor-free by adoptive transfer were tested 38 days later for evidence of heightened antitumor immunity. Two experiments illustrated in table 4 were designed to test whether rejection of 10^4 or 10^5 line-10 cells by adoptive immunity leads to an increased systemic immunity capable of rejecting 10^6 line-10 cells inoculated in the contralateral side. In control animals, each of which was given immune cells iv and challenged 38 days later with 10^6 line-10 cells, the ED$_{50}$ of transferred immune spleen cells was 76×10^6. Animals rejecting an initial challenge of 10^4 or 10^5 line-10 cells did not show increased resistance to the second challenge of 10^6 line-10 cells, as judged by the ED$_{50}$ of 72 and 76×10^6 immune spleen cells, respectively. The suppression of the growth of the second challenge reflected the numbers of immune spleen cells transferred and was independent of the rejection of a previous challenge. These findings thus suggest that rejection of 10^4 or 10^5 line-10 challenge by adoptive immunity did not depend on the host immune response to the tumor.

Local Immune Stimulation and Tumor Rejection by Adoptive Immunity

Failure to demonstrate augmented host immunity after tumor rejection by adoptive immunity did not exclude the possible significance of a secondary local immune stimulation to tumor rejection. It was possible that the transferred immune cells were stimulated and proliferated at the site of tumor inoculation and that this was essential to initiate tumor suppression. To investigate this possibility, we determined by titration the number of immune spleen cells required to suppress a line-10 inoculum consisting of a mixture of live and irradiated cells. Irradiated line-10 cells are not tumorigeneic but retain tumor-specific rejection antigens (*30, 31*). Addition of irradiated cells to the tumor inoculum would provide more tumor-specific rejection antigen than that present in the inoculum with no irradiated cells. Experiments were done to determine the ED$_{50}$ of immune spleen cells required to suppress a tumor inoculum consisting of live line-10 cells alone or of a mixture of live and irradiated line-10 cells. Table 5 shows that the ED$_{50}$ of immune spleen cells in guinea pigs challenged with a mixture of 10^4 live and 99×10^4 irradiated line-10 cells was 18×10^6, whereas the ED$_{50}$ of 25 and 71×10^6 were computed for guinea pigs challenged with 10^4 or 10^6 live line-10 cells, respectively. The ED$_{50}$ of immune cells in animals challenged with 10^6 live cells and in those challenged with a mixture of 10^4 live and 99×10^4 irradiated line-10 cells (a total of 10^6 cells) were significantly different. This finding suggests that the irradiated tumor cells were not the targets for transferred immune cells. While the ED$_{50}$ obtained when irradiated cells were added to live cells (18×10^6) was not significantly different from that obtained with live cells alone (25×10^6), the decrease in number of immune cells required to reject the tumor challenge containing irradiated cells suggested that antigenic stimulation at the local level might be important to tumor suppression.

TABLE 4.—*Analysis of systemic tumor immunity in guinea pigs which previously rejected a line-10 tumor challenge*[a]

[a] Each guinea pig was given immune spleen cells iv suspended in 2 ml of RPMI-1640 medium and was challenged id on the same day with ascites line-10 cells in 0.1 ml of medium 199.

[b] No. of animals with tumor/No. tested 38 days after challenge.

[c] 20,000 rad of γ-irradiation.

Biological Characteristics of Systemically Transferred Immunity

We estimated the proportion of transferred cells that found access to the challenge site and participated in tumor suppression. In preliminary experiments, we compared numbers of immune spleen cells (ED_{50}) required when administered iv and by direct mixing with tumor inoculum to achieve the same level of antitumor effect. However, comparison of the antitumor effect by different routes of administration was complicated by the fact that normal spleen cells suppressed tumor growth. This suppression as manifested by delayed appearance of palpable skin tumors was minimized by use of a population of effectors obtained from fractionation of spleen cells on a Percoll gradient. Spleen cell preparations contained approximately 50% lymphocytes. The viability by trypan blue exclusion was routinely 65–75%. Fraction I from the Percoll gradient contained 90% viable cells, although lymphocytes remained at 50%. Fraction II from the same Percoll gradient consisted of mostly dead cells (viability, <40%). The numbers of viable cells recovered in fractions I and II were 70 and 10% of the input, respectively.

Preliminary titrations indicated that the ED_{50} of unfractionated and fraction I immune spleen cells required for suppression of 10^5 line-10 cells by iv transfer were comparable. Therefore, local and systemic transfers of immunity were compared with fraction I of Percoll-fractionated immune spleen cells. The results (table 6) show that the ED_{50} of immune cells given iv was about 71 times greater than that obtained by direct mixing in the suppression of a line-10 challenge of 10^5 cells. This experiment was repeated once, and the ED_{50} computed for iv transfer was 36 times that for direct mixing (data not shown). These results suggest that there is no significant accumulation of iv transferred cells at the tumor inoculation site.

To test this further, we designed an experimental protocol in which the adoptively transferred immunity (100×10^6 immune spleen cells iv) was assessed by challenging the recipient with a single injection of 10^7 line-10 cells or with 10 injections of 10^6 line-10 cells spaced at least 25 mm apart from each other. The results of the two identically designed experiments I and II are shown in table 7. Challenge with 10^6 or 10^7 line-10 cells led to progressive tumor growth in all control animals (no immune cells transferred). Challenge with 10 injections of 10^6 line-10 cells at 10 separate sites in control animals was followed by tumor growth at all sites, except that 1 guinea pig of experiment I did not show a palpable tumor for 1 of the 10 challenges by the end of the experiment (42 days). In guinea pigs given 100×10^6 immune spleen cells iv, the growth of a 10^6 line-10 challenge was completely suppressed, whereas a 10^7 line-10 challenge at a single skin site grew in each of the 5 animals and in 3 of the 5 animals in experiments I and II, respectively. When 100×10^6 immune spleen cells were transferred iv, growth of the tumors at 10 challenge sites per recipient was suppressed in most animals. In experiment I, 1 guinea pig that was given immune cells and challenged at 10 skin sites had 1 small papule palpable at 14 days, and 3 additional tumors developed at day 28 and persisted until the end of the experiment (42 days). In experiment II, 1 animal that was given immune cells and challenged at 10 skin sites developed 2 small papules that did not grow progressively but did persist for the length of the experiment (42 days).

TABLE 6.—*Comparison of local and systemic adoptive immunity to a dermal line-10 challenge in guinea pigs*[a]

Spleen cells				
Mode of transfer[b]	Immune status	No. transferred × 10^{-6}	Tumor incidence[c]	ED_{50}
		0	6/6	
Local	Normal	2	6/6	
	Immune to line-1	2	6/6

	"	50	6/6	
	"	25	6/6	
	"	12.5	5/6	

[a] Each guinea pig received a 10^5 line-10 id challenge in 0.1 ml of medium 199 on the day of adoptive transfer.

[b] Local was by direct mixing with line-10 cells before id inoculation; systemic was iv in 2 ml RPMI-1640 medium.

[c] No. of animals with tumor/No. tested 49 days after challenge.

TABLE 7.—*Expression of tumor immunity in skin of guinea pigs receiving immune lymphoid cells iv*[a]

Expt. No.	No. of immune spleen cells transferred × 10^{-6}	Tumor incidence[b] after No. of line-10 challenges × dose of:		
		1×10^6	10×10^6[c]	1×10^7
I	0	6/6	6/6	6/6
	100	0/6	1/5[d]	5/5
II	0	6/6	6/6	6/6
	100	0/6	1/6[e]	3/5

[a] Each guinea pig was given immune spleen cells iv in 2 ml of RPMI-1640 medium and was challenged id on the same day with ascites line-10 cells in 0.1 ml medium 199.

[b] No. of animals with tumor/No. tested.

[c] When multiple challenges were administered, the distance between the two sites was ≥25 mm.

[d] One animal had a static small papule at 14 days; 3 additional palpable tumors appeared at 28 days and persisted for the entire experimental period of 42 days.

[e] One animal developed 2 small papules that did not grow progressively but persisted throughout the experiment (42 days).

In a different experimental protocol, we further investigated the significance of attraction and accumulation of iv transferred immune cells in the area of dermal tumor challenge. This experiment was designed to test whether the presence of 10^7 line-10 cells in the skin could abrogate the antitumor activity to 10^6 line-10 cells inoculated adjacent to or distant from it. To avoid possible growth inhibition or enhancement of the 10^6 line-10 inoculations in animals that had extra tumor burden, we included groups of guinea pigs in which the inoculation sites of 10^7 line-10 cells were surgically excised 3 days after the onset of the experiment. Results show that suppression of the growth of 10^6 line-10 tumor cells by adoptive immunity was not influenced by the presence of 10^7 line-10 cells adjacent to it (table 8). These

TABLE 8.—*Lack of specific attraction at id tumor challenge site in guinea pigs given immune lymphoid cells iv*

No. of immune spleen cells transferred on day 0 ×10^{-6}	Tumor incidence[a] when line-10 challenge doses were given on the:		
	Left flank[b]		Right flank: 10^6

[b] When 2 injections per flank were given, the distance between inoculation sites was ≥25 mm.

[c] SR=surgically removed 3 days after challenge.

results suggest that the iv transferred cells were not attracted specifically to the tumor challenge skin site.

DISCUSSION

Impetus for the quantitative analysis of adoptive immunity reported here came from our previous study of interactions between immune lymphoid cells and line-10 targets (*16*). We found that immune cells that conveyed adoptive immunity possessed receptors for tumor-specific rejection antigens and reacted in vitro with cultured line-10 hepatoma cells, but such interactions did not lead to target cell destruction in vitro. In contrast, an immune lymphoid cell population mediating in vitro cytotoxicity failed to confer adoptive protection to line-10 challenge in vivo. The apparent discordance between the two observations led us to conclude that data from adoptive transfer may be required to form a basis for mechanistic studies of in vivo antitumor immunity. To facilitate studies on mechanisms of tumor immunity, we established quantitative relationships between effector cells and tumor targets in adoptive transfer experiments.

Results of two-dimensional titrations revealed that tumor rejection was an exponential function of immune lymphoid cell dose. The logarithmic values of the two variables were correlated linearly, with a slope of approximately 2.51. The exponential relationship between the numbers of immune lymphoid cells and the doses of tumor cells suppressed in adoptive immunity is of theoretical interest. The transferred immune cells may be restimulated and expanded, and/or the recipient may be immunized by the tumor challenge. Increasing tumor cell challenge doses would provide increased amount of antigen and perhaps a greater immune response. Thus the rejection of a higher dose tumor challenge would require proportionally fewer transferred immune cells. For this hypothesis to be validated, one must demonstrate that a secondary immune stimulation and/or the host primary immune response are important in the tumor suppression by adoptive immunity. A report by Alexander et al. (*32*) emphasized the role of the host immune response in tumor rejection by transferred immune lymphocytes in a rat fibrosarcoma model. We have taken a different approach and have examined whether heightened immunity existed in guinea pigs that had rejected a tumor challenge by adoptive immunity. The data presented in table 4 showed quantitatively that the ability of the guinea pig to suppress the growth of a second line-10 challenge (10^5 ascites tumor cells) was a function of transferred immune cells and was not influenced by tumor doses that had been previously . These data suggest that suppression of id line-10 rejected. These data suggest that suppression of id line-10 tumor challenges by the transferred immunity in guinea pigs was independent of development of systemic immunity in the recipients. However, we only examined the host response to 10^4 and 10^5 line-10 challenge doses. Our data do not exclude the possibility that greater systemic antitumor immunity is produced by higher challenge doses. The significance of the immunity developed in the recipient to the tumor eradication by adoptive immunity can be elucidated only py performing adoptive transfer in immunologically compromised hosts, since the immunity developed could be interpreted as a consequence rather than as a "cause" of the tumor rejection by adoptive immunity.

While development of systemic immunity did not seem to contribute to the tumor rejection in animals receiving immune cells at the doses of challenge cells tested, a local secondary immune stimulation at the tumor challenge site may be important in explaining the exponential relationship between immune lymphoid cells and tumor rejection. To test this possibility, we took advantage of the fact that irradiated line-10 cells are not tumorigeneic but retain their antigenicity (*30, 31*). Thus we analyzed quantitatively the rejection by adoptive immunity of a 10^4 line-10 cell inoculum in the presence of 99×10^4 irradiated tumor cells. Adding irradiated cells to the tumor inoculum was reported to be tumor enhancing, especially when the number of live tumor cells was relatively small (*33*). Indeed, we found that the mixtures of live and irradiated line-10 cells grew more rapidly than the same number of live cells alone. The enhancement was manifested by an earlier appearance of a palpable skin tumor. The numbers of immune cells required to suppress the growth of tumor challenges in 50% of the recipients with and without the presence of irradiated cells were 18 and 25×10^6, respectively (table 5). The difference between the numbers of immune cells required, however, is not statistically significant. Close scrutiny of experimental data revealed that animals receiving 25×10^6 immune spleen cells, either 1 of 12 or 7 of 12 developed palpable tumors after challenge with 10^4 line-10 cells admixed with 99×10^4 irradiated cells or with 10^4 line-10 cells alone, respectively. This difference could argue that increased antigenic stimulation did contribute to the tumor rejection. For the investigation of the role of antigenic stimulation at the tumor challenge site, a detailed quantitative analysis of the effect of various combinations of live and irradiated line-10 cells may be more revealing.

Much work has been done on mechanisms of passive transfer of delayed hypersensitivity reactions with radioactive isotope-labeled lymphoid cells. It is apparent that only a small proportion of the transferred cells is present in the reaction site at any particular time. It has thus been concluded that the transferred cells are not always attracted specifically nor are they required in large numbers at the site for a positive skin reaction (*34*). Our interest in studying the behavior of immune lymphoid cells after adoptive transfer was stimulated by the observation that, for the same level of tumor suppression, the number of immune lymphoid cells required when mixed directly with tumor cells was only a small fraction of the number needed when given iv. This observation suggests that iv transferred immune cells may not be always accessible to the tumor challenge site and that tumor rejection might be initiated by a small fraction of transferred immune cells.

To investigate more directly whether the transferred immune cells are specifically attracted to the tumor challenge site, we did the experiments described in tables 7 and 8. Our approach has the advantage of examining the overall biological effect of adoptive antitumor immunity and of avoiding pitfalls associated with radioactive isotope labeling [discussed extensively in (*35*)]. Our early experiments indicated that 100×10^6 immune spleen cells were sufficient to suppress the growth of 10^6 but not of 10^7 line-10 cells inoculated at a single skin site. If the limited capacity of the adoptive immunity to reject 10^7 line-10 cells is due to the lack of specific attraction at the challenge site rather than due to insufficient numbers of immune cells available in the recipient, one would expect that a total of 10^7 line-10 cells could be rejected, provided that they were divided into multiple small doses and inoculated at separate skin sites. Alternatively, if specific attraction of immune cells to the tumor challenge site played a significant role in the rejection of the tumor, one would expect that 10^6 line-10 cells would not be rejected when implanted next to a skin site where a large dose (10^7) of the same tumor cells was present. The results of the two types of experiments clearly demonstrated that transferred immune cells were not necessarily attracted specifically to the tumor inoculum.

It appears that expression of transferred immunity at separate skin sites was independent. Since multiple tumor challenges were spaced at least 25 mm apart from each other, these results did not exclude the possibility that specific attraction might have taken place near the challenge sites. For further documentation of this possibility, it will be necessary to perform adoptive transfer experiments with multiple tumor challenges separated by graduated distances.

As regards the distribution of transferred lymphoid cells in syngeneic recipients, previous studies showed that within 24 hours of transfer, more than 80% of the labeled cells were found in internal organs including liver, spleen, lung, and heart (*36, 37*). Evidence also indicated that many of these cells were functionally damaged and therefore taken up by the reticuloendothelial system within hours of transfusion. A small proportion (1-2%) of transferred cells was present in the circulation at 24 hours, and this appeared to correlate well with the number of transferred cells detected in delayed hypersensitivity lesions (*36*). These findings and results of the present study indicate that the immune cells required to initiate tumor suppression at the skin site in our system must have been a minute fraction of the iv transferred cells. In the present study we observed that a 10^7 line-10 challenge dose was invariably rejected by 400×10^6 immune spleen cells. Our spleen cell suspension contained approximately 50% lymphocytes, of which probably less than 10% were specifically immune to the tumor. In the recipient, we may assume that less than 10% of the transferred cells were distributed in the skin. A 25-mm-diameter area represents approximately 2% of the skin of an adult guinea pig. If these estimations are valid, the number of immune cells required to initiate the suppression of a dose of 10^7 line-10 cells would be less than 0.04×10^6.

Certain conclusions can be drawn from this quantitative study of adoptive immunity: 1) The quantitative relationship between transferred immune lymphoid cells and tumor challenge doses is exponential; i.e., a twofold increase in immune cells leads to an increased resistance of 5.62-fold tumor challenge dose. 2) Within the line-10 challenge doses analyzed in this study, tumor suppression by adoptive immunity reflects the intrinsic characteristics of the immune cells and is independent of the development of a primary immune response in the recipient. 3) Success of tumor suppression is influenced not only by the total tumor burden but also by the distribution of the tumor in the recipient. 4) Lack of specific attraction of iv transferred immune lymphoid cells at the tumor challenge site suggests that only a small proportion of the transferred lymphoid cells participates in initiating tumor suppression.

Esophageal Carcinogenesis in F344 Rats by Nitrosomethylethylamines Substituted in the Ethyl Group[1,2,3]

William Lijinsky,[4] Joseph E. Saavedra,[4] Melvin D. Reuber,[4] *and* Sandra S. Singer[4]

ABSTRACT—The carcinogenic activity in male F344 rats of five nitrosomethylalkylamines related to nitrosomethylethylamine has been examined. All rats were tested by administration of controlled doses of the compounds in the drinking water. Nitrosomethylbenzylamine was the most potent carcinogen of the five, causing death of most animals with tumors of the upper gastrointestinal tract (mainly the esophagus) within 6 months after a total dose of 0.2 mmol. The remaining compounds, all of which can be considered true derivatives of nitrosomethylethylamine, were less potent than nitrosomethylbenzylamine but also induced a high incidence of tumors of the esophagus. Nitrosomethyl-2-phenylethylamine and nitrosomethylneopentylamine were of comparable potency, while nitrosomethyltrifluoroethylamine was considerably less potent, as measured by the time to death with esophageal tumors. Deuterium-labeled nitrosomethylethylamine, in which deuterium replaces hydrogen on the β-carbon atom of nitrosomethylethylamine, induced a high incidence of esophageal tumors as well as liver tumors after administration of identical doses. Reactions on the β-carbon atom of nitrosomethylethylamine might be important as well as oxidation at the α-carbon atoms in determining carcinogenic effects.—JNCI 1982; 68:681–684.

Nitrosomethylethylamine is something of an anomaly among simple aliphatic nitrosamines because it is so much less potent as a carcinogen than is nitrosodimethylamine or nitrosodiethylamine (*1*), although it is presumed to act as they do through oxidation to simple alkylating agents which alkylate nucleic acids, primarily DNA. The asymmetric NMEA would presumably give rise to both methylating and ethylating species. In addition, the activity of NMEA as a carcinogen is not congruent with another general rule proposed by Druckrey et al. (*1*) that asymmetric aliphatic nitrosamines have the esophagus as their target in the rat, whereas the symmetrical nitrosamines have the liver of the rat as their target; NMEA is primarily a liver carcinogen in the rat (*1, 2*).

In the course of studies of the effect of deuterium substitution for hydrogen at various positions in the molecule of NMEA (*2*), we discovered that those deuterated derivatives with deuterium on the β-carbon of the ethyl group gave rise to a significant incidence of esophageal tumors as well as liver tumors. This led us to conclude that oxidation at the β-carbon plays a modifying role in carcinogenesis, as well as the usual oxidation at the α-carbon atoms which is commonly believed to be critical in activation of nitrosamines to their proximate carcinogenic forms. It seemed reasonable to pursue this by examining the effect of substitution of other atoms and groups at the β-carbon on the carcinogenicity of NMEA. A number of derivatives of this nitrosamine were prepared and administered to groups of rats by being dissolved in their drinking water at approximately equimolar doses. The time to death of tumor-bearing rats was then observed. The compounds tested included one with a single substituent, NMPA, and those with all three β-hydrogen atoms replaced, as in NMEA-d_3, NMFA, and NMNA. NMBA was included for comparison, although it is not strictly one of the compounds of this series. The structures of these compounds are shown in text-figure 1.

MATERIALS AND METHODS

Chemicals.—NMEA-d_3: NMEA-d_3 was prepared from acetyl-d_3 chloride, which was formed by heating 16 g (0.25 mol) of acetic acid-d_4 with 56 g (0.4 mol) of benzoyl chloride and distilling the resulting acetyl-d_3 chloride at 48°C. The yield was 12 g (68%). This product (8 g, 0.1 mol) was dissolved in benzene and cooled in ice, and dry methylamine gas was bubbled through the solution until the vapor above was alkaline. The reaction mixture was warmed to room temperature, and the methylamine hydrochloride was filtered off. Evaporation of the benzene left 5.6 g (73%) of *N*-methylacet[D_3]amide, which was spectroscopically identical with the undeuterated compound. This product (8.2 g, 0.11 mol) was dissolved in dry THF (50 ml) and added slowly to a suspension of aluminum lithium hydride (5.7 g, 0.15 mol) in dry THF. The mixture was boiled under reflux for 2 hours, and the excess hydride was destroyed by slow addition of 25 ml ethanol:water (1:1) followed by 25 ml water. The mixture was filtered, and 100 ml brine was added; the mixture was extracted with two treatments of 100 ml ethyl ether. The ethyl ether solution was extracted twice with 100 ml *N* HCl. The combined acid extracts were cooled in ice, 100 ml acetic acid was added, and then 30 g sodium nitrite was added slowly. After a 2-hour reaction, the pH was adjusted to 6, and the solution was extracted six times with 150 ml of methylene chloride. The methylene chloride solution was shaken three times with 150 ml 5% sodium hydroxide solution to destroy any nitrosamide present and was dried, and the methylene chloride was distilled off. The

TEXT-FIGURE 1.—Structures of beta-substituted NMEA.

residual oil was distilled in vacuo, yielding 3.4 g (35%) of deuterated product (bp 60°C at 20 mm Hg). Analysis of the product by high-pressure liquid chromatography showed the presence of the nitrosamine and the absence of any significant impurity that could be the nitrosamide. By UV spectrophotometry, $\lambda_{\max}^{\mathrm{EtOH}}$ $(\epsilon)=347$ nm (94). MS was m/z, 91 (M^+, 100%), 90 (14), 79 (19), 61 (3), 60 (8), and 59 (18). IR spectrophotometry was 1,440, 1,460, and 1,040 cm^{-1} (N—N═O). NMR was δ 2.98, δ 3.68 (sharp s, 3H, CH_3-two rotamers), δ 3.56, and δ 4.12 (b, 2H, $-\underline{CH}_2$-two rotamers).

NMBA and NMPA: NMBA and NMPA were prepared by addition of sodium nitrite to solutions of the secondary amines (Aldrich Chemical Co., Milwaukee, Wis.) in 2 *N* HCl, separation of the nitrosamine layers, and distillation of the nitrosoamines in vacuo. The purity of these compounds exceeded 99% by chromatography. Their physical characteristics and spectral properties have been described (*1*).

NMNA: Methylene chloride (200 ml) was cooled to 5°C and saturated with methylamine gas. A 1-*M* solution of 20 g (0.166 mol) trimethylacetyl chloride (Aldrich Chemical Co.) in methylene chloride was added dropwise. The ice bath was removed, and stirring was continued for 1 hour. The hydrochloride salt was removed by vacuum filtration. The filtrate was washed with 1 *N* hydrochloric acid, followed with aqueous sodium hydroxide and then with water. The solvent was removed on a rotary evaporator, and the product was recrystallized from petroleum ether:THF to give 15.34 g (80%) of white crystalline *N*-methyl-2,2-dimethylpropionamide. The mp was 89–90°C. NMR ($CDCl_3$) was δ 1.18 (s, 9H), δ 2.77 (d, 3H), and δ 6.0 (b, 1H).

A solution of 15 g (0.13 mol) of *N*-methyl-2,2-dimethylpropionamide in 130 ml of THF was reduced to *N*-methyl-*N*-neopentylamine in 76% yield with diborane·THF complex as described by Brown and Heim (*3*). The bp was 85–90°C [in the literature (*4*), 88–90°C]. The amine (7.5 g, 0.074 mol) was nitrosated as described by Büttner and Hünig (*5*). The nitrosamine was obtained in 88% yield. Its bp was 76–77°C at 14 mm Hg (in the literature, 76–77°C at 14 mm Hg). NMR ($CDCl_3$) was δ 0.92, δ 1.03 (s, 9H), δ 3.10 (s, 2.79H), δ 3.81 (s, 0.21H), δ 3.42 (s, 0.14), and δ 3.91 (s, 1.86H). By UV spectrophotometry, $\lambda_{\max}^{\mathrm{EtOH}}$ $(\epsilon)=349$ nm (85). MS was m/z, 130 (M^+, 29%), 115 (7), 85 (8), 74 (8), 73 (12), 70 (15), 57 (100), and 44 (60).

NMFA: *N*-Methyltrifluoroacetamide was prepared from trifluoroacetic anhydride and methylamine in a 94% yield as reported by Pailer and Huebsch (*6*). The mp was 48–49°C (in the literature, 48–49°C). NMR ($CDCl_3$) was δ 2.95 (d, 3H) and δ 6.46 (b, 1H).

Methyl-2,2,2-trifluoroethylamine hydrochloride was prepared in a 67% yield from the aluminum lithium hydride reduction of *N*-methyltrifluoroacetamide as described by Bissell and Finger (*7*). The mp was 218–221°C (in the literature, >200°C). NMR ($CDCl_3$) was δ 2.88 (s, 3H) and δ 3.98 (q, 2H).

Methyl-2,2,2-trifluoroethylamine hydrochloride (10 g, 0.075 mol) was nitrosated according to the procedure of Bissell and Finger (*7*). Distillation of the crude product at 1 atmosphere gave 7.1 g (76%) of pure NMFA. The bp was 135–136°C (in the literature, 131–133°C). IR spectrophotometry (film) was 1,475, 1,340, 1,216, 1,170, 833, and 754 cm^{-1}. NMR ($CDCl_3$) was δ 3.16 (s, 2.4H), δ 3.95 (s, 0.6H), δ 4.23 (q, 0.4H), and δ 4.80 (q, 1.6H). By UV spectrophotometry, $\lambda_{\max}^{\mathrm{H_2O}}$ $(\epsilon)=350$ nm (75). MS was m/z, 142 (M^+, 100%), 110 (11), 83 (33), 73 (37), 69 (18), 59 (18), and 42 (81).

Animal treatments.—Each of the nitrosamines was administered to a group of 20 male F344 rats bred and housed in the barrier-maintained colony of the NCI-Frederick Cancer Research Facility. The animals, 7–8 weeks old at the beginning of the experiments, were housed 4/group in plastic cages with wire mesh bottoms and fed Rockland rat diet (Rockland, Inc., Gilbertsville, Pa.) in pellets ad libitum. As drinking water on each of 5 days of the week, 80 ml of a solution of the appropriate nitrosamine was supplied to each cage; on the remaining 2 days, the animals were given tap water ad libitum, with which they made up for any water deficit. No special group of untreated controls was part of this experiment; however, a continuous group of untreated animals is maintained in the facility, and their incidence of tumors did not differ from that reported for a large group of untreated Fischer 344 rats in various laboratories (*8*).

The period of animal treatment was originally planned for 30 weeks but was shortened in some regimens (such as with NMBA) because the animals began to die earlier. Similarly, we originally planned to supply all of the nitrosamines at equimolar doses, but we had to modify this because the selected concentration (0.34 m*M*) proved toxic with NMNA, NMBA, and NMPA. When the treatments ceased, the animals were allowed to die naturally (a few were killed when moribund) and were thoroughly necropsied; all major tissues and organs, as well as all lesions, were fixed for histopathologic examination.

RESULTS

The treatments given the groups of male rats, the duration of treatment, and the pattern of death of the animals are shown in table 1. Most of the rats died with tumors, usually of the types not found in untreated animals, and the number of each type of tumor induced by the various nitrosamines is shown in table 2.

For comparison, the results of the administration of the parent compound NMEA are given, although they were started 3 years earlier in rats of the same stock and have been reported previously (*2*). All groups of treated animals died at a more rapid rate than untreated rats, presumably because of the tumors induced. When this pattern of death is used as a criterion, although not as a quantitative measure, it appears that NMBA is the most potent carcinogen, since a relatively low dose of this compound led to the earliest deaths with esophageal tumors. NMPA is next in order of potency, followed by NMNA, NMFA, and NMEA and NMEA-d_3, which are about equal.

As might be expected, the lower dose of each nitrosamine that was administered at two doses was less effective than was the higher dose, although this difference was much more marked with NMFA than with NMPA. Although the lower dose of either NMPA or NMFA was 40% that of the higher one, there was very little difference in mortality between the 2 groups treated with different doses of NMPA, but there was a large difference between the 2 groups treated with different doses of NMFA.

Except with NMEA and NMEA-d_3, the tumors induced by the nitrosamines were all in the upper gastrointestinal tract. The tumor incidences in all of the groups were virtually 100%. NMEA induced almost exclusively liver tumors, while NMEA-d_3 induced a high incidence of esophageal tumors as well as liver tumors. Most of the treatments were so tumorigenic that few of the spontaneous tumors commonly found in untreated animals of this strain (*8*) were seen.

DISCUSSION

The mechanism of carcinogenesis by NMEA is not known, nor is it known for any N-nitroso compound, although it is suspected that oxidation of the molecule to an intermediate which, directly or indirectly, alkylates DNA at critical sites, is responsible. An explanation for the lesser activity of NMEA than of nitrosodimethylamine or nitrosodiethylamine might lie in the possibility of oxidation of NMEA to both a methylating and an ethylating agent, each of which might be formed in a lower concentration than if it were formed from the symmetrical compounds. Studies have not yet been done of the relative extents of methylation and ethylation of NMEA in vivo. One interpretation of our earlier results in which selectively deuterium-labeled NMEA were used is that ethylation is a more effective carcinogenic

event than is methylation (*2*). In those experiments in which the doses were 0.34 mM, few or no esophageal tumors were induced except by those derivatives with deuterium in the beta position of the ethyl group. Only at much higher doses, e.g., 1.5 mM, was a significant incidence of esophageal tumors (as well as liver tumors) induced by NMEA itself (*9*). This might lead to the conclusion that tumor induction in the esophagus is by some minor pathway that is only revealed at higher concentrations or when other pathways are overwhelmed.

This conclusion is, to some extent, borne out by the present experiments in which substitution on the β-carbon atom of the ethyl group of NMEA results in induction of tumors of the esophagus. The effect of substitution of deuterium at this position is to retard oxidation at the β-carbon. However, the presence of deuterium on the β-carbon atom of NMEA did not greatly affect the tendency of this compound to induce liver tumors in rats, since the survival and liver tumor incidence of the rats treated with NMEA or NMEA-d_3 did not differ much.

Deuterium labeling at the beta position of NMEA only slows down oxidation at that position, whereas substitution of three fluorine atoms or three methyl groups at that position can be expected to abolish oxidation. Consonant with this, NMFA and NMNA are both more potent esophageal carcinogens than is NMEA-d_3. Since NMNA is more effective than NMFA, it must be assumed that more is involved in the induction of esophageal tumors than the prevention of beta oxidation of the ethyl group, and this might affect the rate of alpha oxidation of the ethyl group. However, nitrosodiethylamine, which can undergo beta oxidation as easily as can NMEA, induces a high incidence of esophageal tumors in rats, even at low doses (*10*).

A reasonable conclusion might be that in the rat esophagus the profound effect of the NMEA substituted on the β-carbon atom might be due to production of a methylating agent by oxidation of the ethyl group at the alpha position. The nature of the substituent on the β-carbon could well determine the rate at which the methylating agent is produced in the esophagus, and hence the extent to which alkylation of DNA (or other critical macromolecule) occurs, and thereby its effectiveness in inducing esophageal tumors would be determined. This sequence has been suggested by some preliminary studies by D. P. Kleihues, University of Freiburg, Federal Republic of Germany, who has studied primarily NMBA. He found, as we report here, that NMBA is the most potent esophageal carcinogen among the nitrosamines examined in rats. The reason why none of these compounds induces liver tumors in rats might be related to an inability to oxidize the β-carbon atom of the ethyl group, although the reasons might be more complex. Certainly, nitrosodiethanolamine is purely a liver carcinogen in rats, but it is enormously weaker than is nitrosodiethylamine (*1*, *11*).

The failure of most of the beta-substituted NMEA to induce liver tumors in rats is surprising since the beta-substituted NMEA appear to methylate DNA in vivo as readily in rat liver as in the rat esophagus (*12*). Nitrosomethylcyclohexylamine, a potent esophageal carcinogen in rats (*13*, *14*), was shown to methylate DNA in the liver at the 7-position of guanine much more readily than it alkylated nucleic acids in the esophagus (*15*), but it did not give rise to liver tumors.

There is much less evidence that alkylation by the larger moiety of beta-substituted NMEA occurs, although in some studies oxidation of the methyl group to formaldehyde predominates over oxidation of the α-carbon of the larger group (*16*). However, oxidation to a methylating agent might well be the important reaction in carcinogenesis by these compounds in the esophagus. There are some exceptions to such a generalization, e.g., the carcinogenic action of nitrosomethylaniline. This compound is an esophageal carcinogen of reasonable potency in rats, although it is somewhat weaker than its analog nitrosomethylcyclohexylamine (*13*). Nitrosomethylaniline is not metabolized to a methylating agent, and it is difficult to conceive that it could be. Therefore, the mechanism of action of nitrosomethylaniline as an esophageal carcinogen in rats seems not to be through methylation of DNA in the esophagus. This observation suggests the possibility of alternative mechanisms by which the beta-substituted NMEA induce esophageal cancer in rats.

Induction and Transplantation of Murine Skin Cancers Induced by Methoxsalen Plus Ultraviolet (320–400 nm) Radiation [1,2,3]

M. L. Kripke, [4] **W. L. Morison,** [4] ***and* J. A. Parrish** [5,6]

ABSTRACT—Properties of skin tumors resulting from treatment of mice with ip methoxsalen plus UVA (320–400 nm) radiation (PUVA) were compared to those of skin tumors induced by UVB (280–320 nm) radiation. Repeated treatment of C3H/HeN murine mammary tumor virus-negative (C3H⁻) mice with PUVA produced both fibrosarcomas and squamous carcinomas that were indistinguishable morphologically from UVB-induced tumors. Fragments of 12 primary PUVA-induced tumors were transplanted into normal and immunosuppressed syngeneic recipients, and all grew progressively. In contrast, 19 primary tumors induced by repeated exposure of C3H⁻ mice to UVB grew only in the immunosuppressed mice and not in the normal recipients. The growth of graded doses of cells from 5 PUVA-induced tumors was compared in normal and UVB-irradiated recipients. No preferential growth in UVB-irradiated mice was observed, even though this is characteristic of UVB-induced tumors. Thus PUVA-induced tumors do not appear to have the same antigenic properties as UVB-induced tumors.—JNCI 1982; 68:685–690.

The cutaneous responses to treatment with the chemical photosensitizer methoxsalen followed by exposure to UVA radiation (referred to by the acronym PUVA) are similar in many respects to those observed after exposure to UVB radiation. Both modalities produce erythema, increased pigmentation, epidermal hyperplasia, and cell injury (*1–4*). Furthermore, both UVB radiation and PUVA treatment (*5, 6*) are carcinogenic in mice. In humans, the carcinogenicity of these treatments has not been as firmly established, but UVB radiation is probably responsible for sunlight-induced skin cancer (*5*), and PUVA therapy is associated with a marked increase in the incidence of skin cancer in patients receiving this treatment for skin disease (*7*). Both types of treatment damage DNA directly, although the molecular lesions produced in DNA are quite different. Thymine dimers are probably the most important lesion induced by UVB radiation (*8*), whereas PUVA treatment produces monofunctional adducts and cross-links in DNA (*4*).

Because of the similarities in the biologic responses of skin to PUVA and UVB radiation, we were interested in comparing the antigenic properties of the tumors induced in mice by chronic treatment with these agents. Previous work has established that skin tumors induced in C3H⁻ mice by UVB radiation have two unusual antigenic properties. 1) These tumors are highly antigenic, and most are rejected immunologically upon transplantation to normal syngeneic recipients (*9–11*). 2) These tumors will grow progressively in UVB-irradiated syngeneic mice because of the presence in the UVB-exposed animals of regulatory suppressor T-lymphocytes that specifically inhibit the immunologic rejection of these tumors (*12–14*). In these experiments, we have induced skin tumors in C3H⁻ mice by repeated treatments with PUVA and have examined some of the antigenic properties of these tumors in transplantation tests. Specifically, we have compared the growth of fragments of primary PUVA-induced and UVB-induced tumors transplanted into normal and immunosuppressed syngeneic recipients. In addition, the growth of graded doses of cells from PUVA-induced tumors was compared in normal and UVB-irradiated hosts.

MATERIALS AND METHODS

Mice.—Specific-pathogen-free inbred female C3H⁻ mice were supplied by the Animal Production Area of the NCI-Frederick Cancer Research Facility. They were housed 5 per cage in a room where ambient light was automatically regulated on a 12-hour light–dark cycle.

PUVA treatment.—Methoxsalen (Hoffmann-La Roche, Inc., Nutley, N.J.) was administered by ip injection of 0.5 ml of an 0.8-mg/ml solution of drug in saline containing 5 mg methylcellulose/ml. The solution was made up weekly and stored in dark bottles at 4°C. One hour after the injection of the drug, the mice were exposed to UVA radiation from a bank of 6 PUVA fluorescent bulbs (Sylvania, Danvers, Mass.) filtered through 0.5-mm Mylar to eliminate wavelengths shorter than 320 nm (*15*). The spectral irradiance of the source was measured with a cosine-corrected UV spectroradiometer system (International Light, Inc., Newburyport, Mass.), and measurements of the irradiance were made for the integrated 320- to 400-nm band with a WBS 350 SEE 400 detector. Over this wavelength range, the

[6] We thank Ms. Dolores Winterstein, Mr. Jeffrey Linebaugh, and Mr. Thomas Farris for their excellent technical assistance and Dr. Melvin Reuber for the histopathologic studies.

average incident dose rate was approximately 10 J/m^2/second.

The mice were housed on a shelf 20 cm below the fluorescent bulbs, and the cages were rotated systematically along the shelves before each treatment to compensate for the variations in irradiance along the length of the bulbs. The dorsal fur was removed from the animals with electric clippers (#40 blade) once per week, and the PUVA treatments were administered five times per week, beginning when the mice were 7 weeks of age. The animals were inspected once per week for tumor development, and the primary tumors were measured weekly. Upon reaching a size of approximately 10×10 mm in diameter, the tumors were removed for histologic examination and transplantation.

UVB treatment.—The mice were exposed to UVB radiation from a bank of FS40 sunlamps (Westinghouse, Bloomfield, N.J.) three times per week, as described previously (*10*). The average incident dose rate (non-cosine corrected) was 1 J/m^2/second, as measured by a Hewlitt-Packard radiant flux detector (model 8344A) with a sensitivity of 0.1 μV/μW/cm^2. Approximately 80% of this radiation is emitted in the wavelength range from 280 to 340 nm, with the peak emission at 313 nm. For tumor induction, each UVB treatment was of 10-minute duration; for tumor transplantation studies, the mice were treated for 60 minutes, three times per week, for at least 12 weeks.

Immunosuppression.—C3H$^-$ mice were immunosuppressed by thymectomy at 4–5 weeks of age, followed 2–4 weeks later by whole-body exposure to 450 R of X-radiation from a Philips MG301 X-ray unit. The mice were used in experiments 24 hours after X-irradiation and are referred to as ATX mice.

Tumor transplantation.—Tumors were removed aseptically and trimmed to remove necrotic areas and connective tissue. Fragments approximately 1 mm^3 in size were cut with a scalpel and implanted sc with a trocar through a small incision in the inguinal region of normal and ATX recipients.

Tumor cell suspensions were prepared from minced tumor tissue by digestion with collagenase, followed by incubation in DNase, as described by Peters et al. (*16*). This procedure resulted in single cell suspensions of greater than 90% viability, as judged by trypan blue exclusion. These suspensions were injected sc near the inguinal region of UVB-irradiated mice and age-matched unirradiated control animals. UV irradiation was not continued after the injection of the tumor cells. Recipient mice were examined weekly, and the tumors were measured in three perpendicular diameters.

Histologic examination.—Samples of the primary tumors were fixed in Bouin's solution, embedded, sectioned, and stained with hematoxylin and eosin. Diagnosis of histologic type was made on coded samples by a board-certified laboratory animal pathologist.

RESULTS

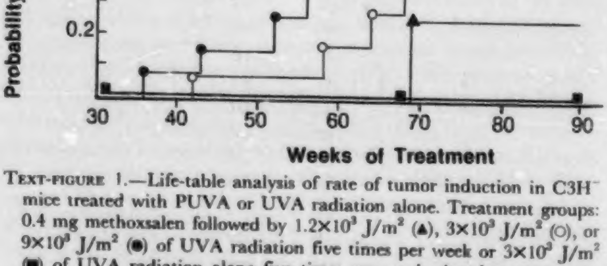
PUVA Carcinogenesis

Following ip injection with 0.4 mg methoxsalen, groups of 25 mice each were treated with three different doses of UVA radiation. The highest dose (9 kJ/m^2), which was delivered in 15-minute exposures, was below the minimum dose that produced visible phototoxicity in a 4-week pilot study. None of the animals in the carcinogenesis study exhibited any visible signs of phototoxic damage during the experiment. The life-table analysis of the rate of tumor induction by the three doses of PUVA is presented in text-figure 1. With these treatment regimens, the latent periods for tumor development were extremely long, but they appeared to be directly related to the dose of UVA radiation. Mice treated for 90 weeks with methoxsalen alone did not develop skin tumors, nor did mice treated with UVA alone. The total UVA doses given to the 2 UVA control groups were 3.1×10^3 kJ/m^2 over a 68-week period and 1.4×10^3 kJ/m^2 over a 90-week period, respectively.

The details of this experiment and the histologic types of the resulting tumors are summarized in table 1. All of the tumors developed on the backs of the animals; most were classified as fibrosarcomas, and a smaller number were squamous cell carcinomas. These results are reminiscent of the findings with chronic UVB irradiation in this mouse strain (*10*). In fact, when examined microscopically in a double-blind fashion, the tumors induced by PUVA were indistinguishable from those induced by UVB radiation. All mice treated with UVA alone survived for the duration of the study, except for a few animals that developed mammary adenocarcinomas at 1 year of age, a typical occurrence in females of this mouse strain. However, the longevity of the animals given ip injections five times per week with methoxsalen decreased sharply. Whether this decrease resulted from the toxicity of the solution, from the trauma of repeated injections, or both is not known.

Transplantation of Primary Tumors

Fragments of 12 of the 15 primary skin tumors that developed in the PUVA-treated mice were transplanted into



TEXT-FIGURE 1.—Life-table analysis of rate of tumor induction in C3H$^-$ mice treated with PUVA or UVA radiation alone. Treatment groups: 0.4 mg methoxsalen followed by 1.2×10^3 J/m^2 (▲), 3×10^3 J/m^2 (○), or 9×10^3 J/m^2 (●) of UVA radiation five times per week or 3×10^3 J/m^2 (■) of UVA radiation alone five times per week. Another group was treated with 9×10^3 J/m^2 of UVA radiation alone five times per week for 68 wk and developed no tumors.

groups of 4–12 normal and immunosuppressed recipients. Three of the tumors were squamous carcinomas; the remainder were fibrosarcomas. As table 2 shows, all 12 tumors grew progressively in most recipients, regardless of whether they were immunosuppressed. At the same time, UVB-induced tumors with a similar range of latent periods were tested. As expected from previous studies (*9, 10*), fragments of these UVB-induced primary tumors grew progressively only in the immunosuppressed mice and not in the normal recipients.

Growth of PUVA-Induced Tumors in UVB-Irradiated Mice

The experiment reported in table 2 demonstrated that tumors induced by PUVA do not exhibit the same high degree of antigenic strength as those induced by UVB radiation. However, this observation does not rule out the possibility that the PUVA-induced tumors might have antigens that are similar in specificity to those found on UVB-induced tumors, even though the magnitude of the primary immune response induced by these two sets of tumors differs. To test this possibility, we prepared cell suspensions of several of the PUVA-induced tumors and injected them sc into normal and UVB-irradiated mice. Mice exposed to UVB radiation for a 12-week period cannot reject UVB-induced tumors, but they exhibit resistance to the growth of syngeneic tumors induced by other carcinogens (*17*). This resistance appears to be caused by the development of a population of suppressor T-lymphocytes during UVB irradiation that recognizes antigens present on UVB-induced tumors and inhibits the immune response against these antigens (*12–14*). Thus preferential growth of the PUVA-induced tumors in UVB-irradiated mice, relative to their growth in untreated animals, would imply antigenic similarity between these tumors and tumors induced by UVB radiation.

Several such experiments are illustrated in text-figures 2 and 3 and in table 3. Ten independent experiments with five different PUVA-induced tumors were performed. In no instance was the incidence of a PUVA-induced tumor significantly higher in UVB-irradiated mice than in age-matched, untreated recipients. This was true even though in 5 of the experiments the PUVA-induced tumors developed more rapidly and/or with a higher frequency in ATX mice than in normal animals (e.g., *see* text-figs. 2, 3). In

contrast, a cell suspension of a UVB-induced fibrosarcoma, also prepared by collagenase digestion, grew progressively in most UVB-irradiated mice but not in the normal recipients (text-fig. 3B).

DISCUSSION

These studies demonstrate that repeated treatment of C3H⁻ mice over a long period of time with doses of PUVA that were insufficient to produce visual evidence of phototoxicity leads to the development of skin cancers. On the basis of the examination of tissue sections with a light microscope, these skin cancers are morphologically indistinguishable from those induced in this mouse strain by UVB radiation. Both squamous cell carcinomas and fibrosarcomas are produced by the PUVA treatment. Despite the morphologic similarity between PUVA-induced and UVB-induced tumors and despite the many similarities in the biologic effects of these two treatments, the PUVA-induced tumors do not exhibit the same behavior in transplantation tests as that normally observed with UVB-induced tumors.

Upon transplantation of tissue fragments from primary tumors, the UVB-induced skin cancers generally are rejected immunologically by normal syngeneic recipients (*9–11*). In contrast, all of the PUVA-induced tumors grew progressively in normal recipients. Thus by the criterion of the ability to induce complete immunologic rejection in unimmunized syngeneic hosts, the UVB-induced tumors as a group are highly antigenic, but the PUVA-induced tumors are not. It has been reported that, in chemical carcinogenesis, the antigenic strength of tumors induced in mice by 3-methylcholanthrene is directly related to the dose of the carcinogen (*18*). Thus it is possible that had higher, photo-

toxic doses of PUVA been used, the resulting tumors might have been more highly antigenic. However, this possibility seems unlikely since there was no indication that tumors induced by the highest doses of PUVA differed as a group from those induced by the lower doses. Furthermore, in UVB carcinogenesis, the proportion of highly antigenic (regressor) tumors does not change as a function of either latency or carcinogen dose (*19*). In the experiments performed in this study (table 2), the doses of UVB and PUVA were comparable, in that neither agent produced visible acute phototoxic effects and both induced skin cancers with approximately the same range of latent periods. Even under these conditions of similar carcinogenicity, the antigenic strength of the resulting tumors differed dramatically for the two agents.

The PUVA-induced and UVB-induced tumors also differed in their ability to exhibit preferential growth in UVB-irradiated mice, relative to that in normal recipients. This behavior is characteristic of both progressor and regressor UVB-induced tumors (*19*). Most or all fragments of regressor tumors regress when transplanted into normal recipients and grow progressively when transplanted into UVB-irradiated mice. To evaluate progressor UVB-induced tumors, one must compare the rates of tumor growth in normal and UVB-irradiated mice or inject a dose of cells in a single cell suspension that is low enough to produce tumors in fewer than 100% of the normal recipients. When tested in this way, none of the PUVA-induced tumors grew more rapidly or at a higher incidence in UVB-treated hosts than in unirradiated mice. In several instances, the PUVA-induced tumors grew at a submaximal rate in the normal recipients and were capable of exhibiting enhanced growth in immunosuppressed mice. Even under these conditions, no enhancement was observed in the UVB-irradiated recipients. The finding that enhanced growth of UVB-induced tumors is mediated by the presence of immunologic regulatory suppressor cells that are specific for UVB-induced tumors as a group (*12–14*) suggests two possible interpretations. Either the PUVA-induced tumors are devoid of detectable tumor-specific transplantation antigens, or their antigens differ in specificity from those exhibited by UVB-induced tumors. It seems unlikely that the PUVA-induced tumors would be completely nonimmunogenic, because some of them grew to a greater extent in immunosuppressed mice than in normal animals when tested at a limiting dose. However, a formal demonstration that this differential growth is immunologically mediated or that these tumors can immunize against subsequent tumor challenge has not yet been made. Regardless of which interpretation is correct, these results demonstrate that, by this criterion also, PUVA-induced tumors differ from UVB-induced tumors in their transplantation properties.

Two implications can be drawn from this study and, although speculative, deserve consideration. The first relates to the development of nonmelanoma skin cancer in humans undergoing PUVA therapy (*7*) and the observation that these lesions are morphologically similar to sunlight-induced skin cancer (*20*). It could be assumed that PUVA-associated tumors in humans will follow the same relatively benign course and have a low metastatic potential as do sunlight-induced skin cancers. However, although certainly there are differences in skin carcinogenesis between humans and mice with PUVA and UVB, the relevant conclusion to be drawn from the animal experiments is that the morphologic similarity of skin cancers induced by these two agents is not necessarily an indicator of similarity in biologic behavior.

The second implication is related to the origin and nature of tumor-specific transplantation antigens. It is not clear why PUVA treatment induces tumors that have such different antigenic characteristics from those induced by UVB radiation. Although the difference in antigenic strength might be explained by differences in the immunosuppressive properties of UVB and PUVA treatments (*21*), this hypothesis does not account for the apparent difference in specificity between the sets of tumors induced by the two agents. Since the major difference between treatment of mice with PUVA or UVB is the nature of the molecular lesion produced in DNA, this raises the possibility that a particular carcinogen may induce a unique set of tumor-specific antigens, based on the site and/or nature of the initial lesion that it produces in DNA. Although this possibility is highly speculative, recent work suggesting that tumors induced in vitro in epidermal cell cultures by a single dose of UVB radiation may have the same antigenic characteristics as those induced by UV irradiation in vivo (*22*) makes it an intriguing hypothesis for further consideration.

Influences of Age and Anatomical Site on Ultraviolet Carcinogenesis in BALB/c Mice[1,2,3]

Peter Ebbesen[4] *and* **Margaret L. Kripke**[5,6]

ABSTRACT—Young adult BALB/c mice were more susceptible to the induction of skin tumors from FS40 sunlamps than were 18-month-old animals. The relative contributions of tissue and host factors to this difference in susceptibility to carcinogenesis were analyzed by reciprocal grafting of skin between young and old animals, followed by repeated exposures of the grafts to UV radiation. More tumors developed in ear skin grafted to the middorsum of young recipients than in that of old recipients, regardless of the age of the skin donor. These ear skin grafts were more susceptible to tumor induction than were comparable grafts of back skin. When large areas of dorsal skin (16 cm^2) were grafted to young adult mice, very old skin (>2 yr) was more susceptible to tumor induction than skin that was 1 year old at the start of irradiation.—JNCI 1982; 68:691–694

The incidence of nonmelanoma skin cancer in humans increases markedly with increasing age in susceptible populations. Furthermore, these skin cancers frequently occur on parts of the body that are the most heavily exposed to solar radiation (*1*). These observations have been interpreted as indicating that sunlight-induced skin cancer results from the progressive accumulation of actinic damage on sun-exposed parts of the body (*2*). However, the contribution of other factors, such as differences in the intrinsic susceptibility of skin from different sites or of different ages to carcinogenesis or age-dependent differences in host defense mechanisms, has not been ruled out.

To explore some of these possibilities, we have used the system of experimental UV carcinogenesis in inbred mice (*3*). Previous work with chemical carcinogens showed that one can analyze the contributions of various host and tissue properties to carcinogenesis by grafting skin of different sources onto syngeneic recipients and studying the development of tumors in the grafted skin (*4, 5*). In these experiments, we have used this approach to separate the factors of cumulative UV dose, tissue age and site, and host influences to determine whether the skin obtained from mice of different ages possesses intrinsic differences that affect its photocarcinogenic response. In addition, we compared the relative susceptibility to UV carcinogenesis of ear skin and back skin by grafting these tissues onto the backs of syngeneic mice and by exposing the grafts to UV radiation.

MATERIALS AND METHODS

Animals.—Specific-pathogen-free BALB/cAnN mice were supplied by the NCI-Frederick Cancer Research Facility's Animal Production Area. They were given free access to water (10–12 ppm chlorine) and Purina Mouse Chow, except during UV exposure, and were housed in rooms where ambient light was automatically regulated on a 12-hour light–dark cycle.

Skin grafts.—Skin removed from the backs of donor mice was scraped with a scalpel to remove subcutaneous fat and connective tissue. A cork borer was used to cut uniform circular grafts 1.5 cm in diameter. Ear skin was prepared by separation of the anterior and posterior ear surfaces and by removal of the cartilage layer. Both surfaces were used as grafts. The recipients were anesthetized with Diabutal, and graft beds the size of the grafts were cut with scissors in the dorsal skin down to the pannicular layer. The grafts were held in place with four sutures and covered with adhesive bandages for 6 days. Each animal received one graft of ear skin and one graft of back skin. In half of the mice, the ear graft was placed anterior to the back skin graft; in the other half, the position of the grafts was reversed. In one experiment, large squares of back skin (16 cm^2) were grafted onto the recipients. These were held in place with wound clips. To prevent tumors from developing in the recipient mice outside of the graft area, we removed the ears of the recipients. We removed only the fur on the grafted skin before UV exposure.

UV irradiation.—The mice were shaved once a week with electric clippers and were exposed three times per week (Monday, Wednesday, and Friday) to a bank of six FS40 sunlamps (Westinghouse, Bloomfield, N.J.). For the first 8 weeks, the animals were given 30-minute exposures; thereafter, each treatment consisted of a 60-minute exposure. In experiments with the small grafts, UV irradiation began 3 months after grafting; in the experiment with 16-cm^2 grafts, UV treatment was started 10 months after grafting.

The mice were housed on shelves 20 cm below the sunlamps, and the cages were rotated systematically along the shelf before each UV exposure to ensure uniform irradiation over the course of the experiment. The average dose rate of the light source was approximately 2 J/m^2/second, as measured with a non-cosine-correcting Hewlett-Packard radiant flux detector (model 8344A), with a sensitivity of 0.1 μV/μW/cm^2. Approximately 80% of the total energy of the

sunlamps is emitted in the wavelength range from 280 to 340 nm, with a peak emission at 313 nm. The mice were irradiated through wire cage tops that reduced the irradiance by a factor of 2.

The mice were examined weekly for tumor development, and each tumor was measured weekly. The time of tumor appearance was determined retrospectively as the week at which a progressively growing lesion reached a size of 4×4 mm in diameter. When a tumor reached the size of approximately 10×10 mm, the animal was killed and the tumor was fixed in Bouin's solution, sectioned, and stained with hematoxylin and eosin for microscopic evaluation. Only 1 tumor-bearing mouse died before the tumor tissue could be prepared for histologic analysis; all other tumors were evaluated microscopically.

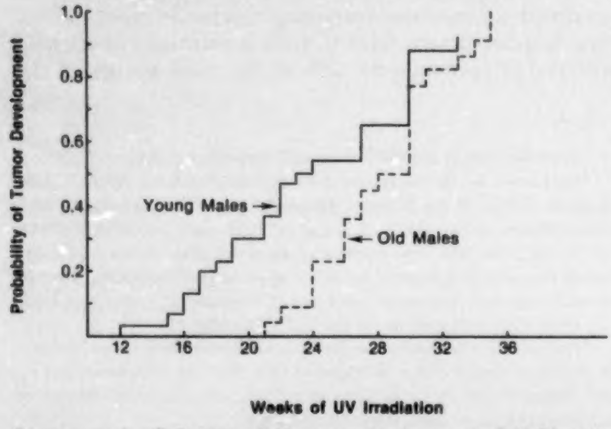
Statistical tests.—The method of Kaplan and Meier (*6*) was used to describe the patterns of tumor development in the carcinogenesis studies. This is a life-table analysis and thus takes into account animals that die before developing a tumor. The results were expressed as the probability that an animal has a tumor as the function of the duration of the experiment. Differences between treatment groups were tested with a censored rank order test according to the method of Breslow (*7*).

RESULTS

Tumor Induction in Young and Old Mice

In the first experiment, the rate of tumor induction in ungrafted skin by UV radiation was compared in young and old BALB/c male mice. The "young" mice were 4–5 weeks old at the time of their first exposure to UV radiation; the "old" mice were 18 months old at the initiation of treatment. Cages of young and old mice were alternated on each shelf of the irradiator to minimize the possibility of inadvertently introducing differences in the exposure of the 2 groups to UV radiation.

As is illustrated in text-figure 1, tumor development began earlier in the young mice than in the older animals, and the patterns of tumor development differed significantly for the 2 groups ($P=0.026$). Thus when mice are given equivalent doses of UV radiation, the younger animals are more susceptible to the carcinogenic effects of UV radiation than are the older mice in that the latent period is shortened. However, by 32 weeks of irradiation, the incidence of tumors was the same in both groups. Most tumors in both groups were squamous cell carcinomas and fibrosarcomas that arose on the ears. No differences were noted between the 2 groups in the proportion of tumors of these two histologic types.



TEXT-FIGURE 1.—Probability of skin cancer development in BALB/c male mice exposed to FS40 sunlamp irradiation three times per week. The young mice (No.=30) were 4 wk old, and the old mice (No.=22) were 18 mo old at the start of the UV treatment. The probability of no difference between these groups is <3%, as determined by a two-tailed *t*-test.

Tumor Induction in Grafted Skin

To determine whether the increased susceptibility of young mice to UV carcinogenesis was an inherent property of the skin, we measured the rate of tumor development for young ear and back skin grafted to young recipients and compared it with that of young ear and back skin grafted to older mice. We performed an analogous experiment with skin from old donors. In this experiment, female mice were used throughout to minimize the problem of damage to grafts caused by fighting among the males. In addition, 4-week-old animals could not be used as graft recipients because of their small size and relative frailty, so the grafting was performed on mice that were 10–12 weeks old. UV irradiation commenced 12 weeks after grafting, so that at the start of UV exposure the young mice were 22–24 weeks old and the old mice were 70 weeks old. Tumor incidence data were collected until week 37 of the UV irradiation, which was the time when the older mice reached approximately 2 years of age.

The tumor incidence data obtained with the ear skin grafts are summarized in table 1. The rate of tumor development was not affected by the grafting procedure. Ear tumors developed on the young mice (group 1) at the same rate as tumors arose on the young ear skin grafted to young recipients (group 2), and tumors appeared on the ears of old mice (group 4) at the same rate as they developed in old ear skin grafted to old recipients (group 5) ($P>0.1$ for both comparisons). Again, the young mice developed tumors more rapidly than the old mice, although this difference was smaller than in the previous experiment (group 1 vs. 4, $P=0.035$; groups 1 and 2 vs. 4 and 5, $P=0.007$). This increased susceptibility to tumor development was not an intrinsic property of the ear skin, however. When young ear skin was grafted to old recipients (group 6), the pattern of tumor development resembled that observed with old skin (groups 4 and 5). Conversely, old skin grafted to young recipients (group 3) assumed the characteristics of young skin with regard to tumor induction (groups 1 and 2). There were no detectable differences in the patterns of tumor induction among groups 1, 2, and 3 or among groups 4, 5, and 6 ($P<0.1$ for all comparisons). However, tumor development differed significantly in old skin grafted to young recipients (group 3) and old skin grafted to old recipients (group 5, $P=0.05$) and in the reverse situation of young skin grafted to old mice (group 6) versus young skin grafted to young recipients (group 2; $P=0.004$). Thus the pattern of tumor development in the grafted ear skin resembled that

TABLE 1.—*Development of UV-induced tumors in grafts of young or old ear skin*

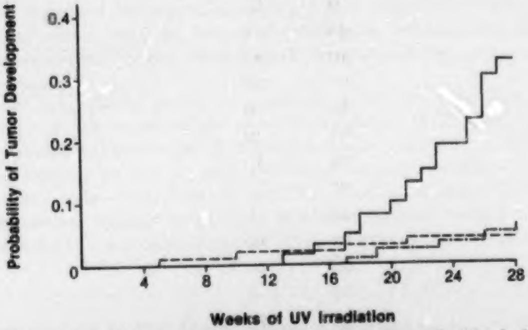
Group No.	Graft	Host[a]	No. of mice at start of UV treatment	No. of mice that died tumor-free	No. of tumor-bearing mice	Tumor incidence, %[b]	Average latency, wk[c]
1	None	Young	40	0	28	70	31
2	Young	Young	41	0	30	73	33
3	Old	Young	40	0	32	80	32
4	None	Old	29	4	16	55	35
5	Old	Old	30	4	16	53	36
6	Young	Old	32	4	15	47	35

[a] Young=20-22 wk at start of UV treatment; old=70 wk at start of UV treatment. All mice were BALB/c females.
[b] Number of mice that developed tumors in 37 wk/number at start of UV treatment.
[c] Week at which the probability of tumor development first equalled or exceeded 0.5.

observed in the recipients and did not resemble the pattern exhibited by the graft donors.

In this experiment, the mice had been grafted with both ear skin and circular pieces of dorsal skin, 1.5 cm in diameter. In spite of the fact that the ear and back skin grafts were approximately the same size and received equivalent exposures to UV radiation, tumors developed in only two of the back skin grafts. In both cases, tumors had appeared earlier in the grafted ear skin. In all groups, tumors appeared only at sites that were exposed directly to UV radiation, i.e., the ears on ungrafted mice and the shaved graft sites of the grafted animals.

In the final experiment, we attempted to compare the susceptibility of adult and senescent mouse skin to photocarcinogenesis. In this instance, large (16 cm^2) squares of back skin were grafted from 10- or 60-week-old female donors onto 10-week-old female recipients. UV irradiation was initiated 45 weeks later, so that the "adult" skin was approximately 1 year old at this time and the senescent skin was 2 years old. During the next 6 months of UV treatment and observation, 4 of the 106 ungrafted adult mice developed back tumors (text-fig. 2). The grafting of skin of the same age as the skin of these animals did not affect this pattern of tumor induction (5 of 91 mice developed skin cancers). However, tumor development was markedly enhanced in the senescent skin (17 of 77 mice developed cancers in the grafted skin). Tumors occurred only on the shaved dorsum of these animals since their ears had been removed prior to irradiation. No differences in the histologic types or proportion of different tumor types were noted among the groups. The ratio of carcinomas:sarcomas was between 3 and 4:1 in all groups.



TEXT-FIGURE 2.—Probability of cancer development in grafted back skin of female BALB/c mice. Ungrafted, 12-mo-old mice (- - - -) (No.=106 at start of UV treatment); mice grafted with 12-mo-old skin (–·–·–) (No.=91 at start of UV treatment); mice grafted with 24-mo-old skin (——) (No.=77 at start of UV treatment). The probability of no difference between the rate of cancer development in old skin versus each of the other groups is <0.1% as determined by a two-tailed *t*-test.

DISCUSSION

These studies indicate that young mice, between the ages of 1 and 6 months, are more susceptible than 18-month-old mice to photocarcinogenesis. This finding agrees with the experiment reported by Blum et al (*8*) in which tumors appeared more readily on the ears of 2- to 3-month-old haired albino mice than on the ears of mice that were 10 months old at the start of irradiation. Forbes et al. (*9*), who compared photocarcinogenesis in hairless mice, made a similar observation, namely, that mice 6 weeks old at the beginning of UV treatment developed tumors more rapidly than 16-week-old animals. The grafting experiment (table 1) suggests, in addition, that this difference is not attributable to some inherent characteristic of the skin but, rather, depends on certain physiologic factors in the host that change as a function of age. This result raises the interesting possibility that during the first half of the life-span of the animals, the age of the host at the time of the first UV exposures may be a determining factor in UV carcinogenesis.

When large grafts were used as a target for UV carcinogenesis, the skin from very old (>2 yr) mice appeared to be more susceptible to transformation than skins from adult animals (text-fig. 2). This was an intrinsic property of the skin since the recipients were all from the same age group. The difference between this result and the result obtained with the small grafts could be due to the very advanced age of the skin used for large grafts; alternatively, the size of the graft could be a determining factor in whether host or tissue influences dominate a given situation. With large grafts, the expression of any host influences might be minimized.

The sources of these differences in host factors and skin properties are not known, but there are many possible candidates for such an effect. For example, the ability to repair certain types of UV-induced damage in DNA changes with age in BALB/c mice (*10*), the proliferative response of epidermal cells to UV radiation differs in animals of different ages (*11*), the activity of various host defense mechanisms changes with age (*12*), and in human skin the mechanical and optical properties change with age (*13*). Regardless of the underlying mechanisms, it is clear that the total cumulative dose of UV radiation and genetic susceptibility are not the only determining factors in photocarcinogenesis. Under conditions in which genetic background, total UV dose, and time for tumor development remained constant, age-dependent host factors and skin properties that influence photocarcinogenesis can be detected. In the study comparing grafted ears and small back-skin grafts, most tumors developed in the ear grafts. Of 93 grafted tumor-bearing mice, all developed tumors on the grafted ear skin, and only 2 of these animals subsequently developed tumors on the grafted back skin as well. Thus the greater susceptibility of ears to photocarcinogenesis relative to back skin in this strain does not result from greater exposure of the ears to UV radiation, as might be expected because of their position relative to the back. Instead, this high frequency of tumor development seems to reflect the fact that ear skin is intrinsically more susceptible to the carcinogenic effects of UV radiation than back skin, most likely because of differences in the optical properties of ears and back skin, resulting from differences in pelage and in thickness of the stratum corneum.

Thus, although UV dose and genetic background clearly influence photocarcinogenesis both in humans (*1*) and experimental animals (*3*), these studies show that other intrinsic properties of the target tissue and age-dependent properties of the host also play a role in the development of UV-induced skin cancers. These findings, coupled with those of Forbes et al. (*9*) demonstrating that photocarcinogenesis also is influenced by the pattern of UV dose delivery, emphasize the complexity of this tumor system and illustrate the difficulties underlying calculations of estimated risks for human photocarcinogenesis.

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

American Cancer Society National Conference—The Primary Care Physician and Cancer

The American Cancer Society, in cooperation with the American Academy of Family Physicians, will sponsor this conference to be held at the Hyatt Regency Washington on Capitol Hill, Washington, D. C., on June 24–26, 1982. The objective of this conference is to provide an increased understanding by the primary care physician of the wide range of medical and psychosocial problems of the cancer patient. The multidisciplinary approach to managing these problems will be stressed.

Attendance is open to members and students of the medical and health-related professions. There is no registration fee; advance registration is requested. For additional information please write to Dr. Nicholas G. Bottiglieri, American Cancer Society Conference, The Primary Care Physician and Cancer, 777 Third Avenue, New York, New York 10017.

Eleventh Annual Meeting of the International Society for Experimental Hematology

Baltimore, Maryland, will be the site of this meeting to be held on August 12–15, 1982. For additional information please contact Dr. Lyle R. Heim, Department of Pediatrics, Texas Tech University, School of Medicine, 4800 Alberta Avenue, El Paso, Texas 79905.

Workshop on "Coagulation, Cancer and Inflammation"

The National Heart, Lung, and Blood Institute, the National Cancer Institute, and the National Institute of Arthritis, Diabetes, and Digestive and Kidney Diseases will sponsor this workshop to be held at the Airlie House, Airlie, Virginia, on September 8–10, 1982. This workshop will address the roles of the coagulation and fibrinolytic pathways, the monocyte and macrophage, and the integrated interactions between fluid phase molecules and cells in the pathobiology of thrombotic disease, cancer, and inflammation.

Those who wish to attend the workshop should notify the National Heart, Lung, and Blood Institute in writing by July 1, 1982, and indicate their specialty and specific research interests. Applicants will be notified of their acceptance by July 15, 1982. For further details or to apply for the conference, please contact Dr. Anne P. Ball, Division of Blood Diseases and Resources, National Heart, Lung, and Blood Institute, Federal Building, Room 5A12, Bethesda, Maryland 20205 (telephone: 301-496-5911).

Approaches to the Management of Pain

The Bay Area Tumor Institute and the East Bay Cancer Program will co-sponsor this conference to be held at Goodman's Hall, 10 Jack London Square, Oakland, California, on September 9, 1982. The conference will deal with the multidisciplinary approach to the management of pain.

For additional information contact Ms. Despina C. M. Johnson, Program Manager, 2844 Summit Street, Suite 204, Oakland, California 94609 (telephone: 415-465-8570).

Eighth Biannual Morris Hepatoma Symposium

This Satellite Symposium of the Thirteenth International Cancer Congress will be held at the Westin Hotel, Fifth Avenue at Westlake, Seattle, Washington, on September 16, 1982.

Additional information may be obtained from Dr. Wayne E. Criss, Morris Hepatoma Program Director, Cancer Center, Howard University, Washington, D. C. 20060 (telephone: 202-636-6351/52).

Fourteenth Meeting of the International Society for Pediatric Oncology (SIOP)

Berne, Switzerland, will be the site of this meeting to be held at the Department of Pediatrics, Inselspital, Berne, on September 21–25, 1982. "New Modes of Therapy and Supportive Care" will be the main theme of the meeting. Reports on current trials and a pathologists' meeting will be included.

For further information please write to Dr. Hans P. Wagner, c/o SPOG, Institute for Clinical and Experimental Cancer Research, Tiefenauspital, 3004 Berne, Switzerland.

Second International Congress of the T. and L. de Beaumont Bonelli Foundation for Cancer Research

"The Role of Viruses in Human Cancer" is the subject of this conference to be held in the Royal Palace, Naples, Italy, on September 23–26, 1982. The purpose of the conference is to provide current results and perspectives in main areas in which viruses have been potentially associated with human malignancies.

Additional information may be obtained from Dr. Errico di Lorenzo, Organizing Secretary, V.le Elena, 80122 Naples, Italy.

Large Bowel Cancer: Biology and Control

An exhibit and brochure, prepared by the National Large Bowel Cancer Project, is available for distribution through the American College of Surgeons. "Finding the Cause," "Current Management," and "Toward the Solution" are the topic areas of this three-panel exhibit and 36-page brochure that are particularly suited for teaching seminars, national meetings, and workshops on cancer of the large bowel.

The exhibit and brochures can be obtained separately or together. There is no fee for either, except for shipping charges. For further information, please contact Ms. Irene J. Diament, Administrative Assistant, Cancer Department, American College of Surgeons, Chicago, Illinois 60611 (telephone: 312-664-4050).

Journal of the National
Cancer Institute

May 1982
Volume 68
Number 5

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $7.00. Subscription price for two volumes per year in the United States, $70.00; foreign, $87.50. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20016.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20016.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols: *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40: 2083–2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221–245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs*. Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Merdicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3–10/Ann Intern Med 1979;90:95–99/Br Med J 1979;1:532–535/ or Lancet 1979;1:428–430).

Heterogeneous Response to X-Ray and Ultraviolet Light Irradiations of Cultured Skin Fibroblasts in Two Families With Gardner's Syndrome[1,2]

Timothy J. Kinsella,[3,4] John B. Little,[3] John Nove,[3] Ralph R. Weichselbaum,[3] Frederick P. Li,[5,6] Robert J. Meyer,[5] David J. Marchetto,[7] *and* W. Bradford Patterson[7]

ABSTRACT—A heterogeneous response to X-ray and far UV (254 nm) light irradiations was found in cultured skin fibroblast lines from 2 separate families with Gardner's syndrome. When compared to 2 normal control cultures and cultures from 2 patients with nonfamilial colon cancer, cultures from 4 clinically affected members of family 1 showed increased sensitivity to the lethal effects of both X-ray and UV light irradiations. These cell lines also showed a delayed pattern of X-ray potentially lethal damage repair (PLDR) and absent UV PLDR. In contrast, cultures from 3 members of family 2 (2 of whom were clinically affected) showed a normal response of survival and PLDR to both X-ray and UV light irradiations. Thus increased sensitivity of cultured skin fibroblasts to X-ray and UV light irradiations was not a consistent in vitro finding in patients with Gardner's syndrome. However, in families with Gardner's syndrome who demonstrate in vitro radiosensitivity, additional studies are needed to assess the usefulness of these techniques in detecting affected individuals prior to the development of colon carcinoma and other manifestations.—JNCI 1982; 68:697-701.

Gardner's syndrome is an autosomal dominant disease characterized by multiple adenomatous polyps of the colon and rectum, associated with osteomas and soft tissue tumors (*1-4*). Affected individuals are markedly predisposed to colon adenocarcinomas. Polyps usually appear during the 2d to 3d decade of life and gradually increase in number over the next 10-15 years. Colonic adenocarcinomas develop at this stage and may be multifocal. Prophylactic removal of the colon is the recommended treatment prior to cancer development.

In vitro sensitivity of cultured skin fibroblasts to X-ray or UV light irradiation has been reported in several genetic diseases with an increased frequency of spontaneous and radiation-induced cancers. These diseases include autosomal recessive disorders such as XP (*5, 6*), AT (*6, 7*), and autosomal dominant retinoblastoma (*8*). A specific DNA repair defect has been identified in XP to explain the phenotypic manifestation of sun sensitivity and the increased frequency of skin cancer (*9*). The increased sensitivity of AT and retinoblastoma may also reflect a DNA repair defect associated with carcinogenesis.

On the basis of the in vitro observation by Danes (*10*) and Kopelvich et al. (*11*), we questioned whether a DNA repair defect might play a role in the cancer development with Gardner's syndrome. Because of the technical difficulties in establishing cell lines from colon epithelium, we chose to measure radiation damage and repair in cultured skin fibroblast lines.

We previously reported an increased sensitivity to both X-ray and UV light irradiations of the cultured skin fibroblasts from 2 affected members of a family with Gardner's syndrome (*12*). This report presents further observations of X-ray and UV light irradiation sensitivity in other members of the previously reported family as well as in a second family with Gardner's syndrome.

MATERIALS AND METHODS

Patients.—A medical history and physical examination were performed on each study patient from families 1 and 2. Special attention was directed toward examination of the skeleton, skin, and subcutaneous tissue. Pertinent diagnostic studies included sigmoidoscopy (with biopsy of polyps), upper gastrointestinal and colon X-rays (with contrast), and plain bone X-rays when appropriate. A pedigree from each family was constructed by interview with the study patients and other family members.

Fibroblast lines.—A 3.0-mm punch biopsy specimen of the skin was obtained from each patient in families 1 and 2 and established in culture in our laboratory and at Meloy Laboratories Inc., Springfield, Va. Control skin fibroblast lines were established in our laboratory from 2 normal donors and 2 patients with sporadic, nonfamilial colon cancer. Skin fibroblast lines from a patient with XP and one with AT were obtained from the American Type Culture Collection, Rockville, Md.

All cell strains were grown in Eagle's minimum essential medium (F-15; GIBCO, Grand Island, N.Y.) supplemented with 15% fetal bovine serum (M.A. Bioproducts, Walkersville, Md.), 50 mg gentamycin/ml (Schering, Bloomfield, N.J.), and 0.9 g of D-glucose and 0.66 mg of sodium pyru-

vate/liter. They were maintained in T-75 flasks (Falcon Plastics, Oxnard, Calif.) in a 5% CO_2–95% air atmosphere at 37°C. The cells were passaged weekly by exposure to 0.25% trypsin in calcium- and magnesium-free Earle's balanced salt solution, usually at a 1:4 dilution. Cell strains were tested prior to passage 15. Gardner's syndrome, AT, XP, and control cells were studied at similar passage levels.

X-ray and UV light irradiations.—X-ray and UV light survival studies were performed by a standard colony formation assay. Cells were detached from the stock cultures with 0.25% trypsin, suspended, and reseeded into 100-mm petri dishes (Falcon Plastics) in numbers calculated to yield approximately 50 macroscopic colonies per dish when the plating efficiency and lethality from X-ray or UV light irradiation were accounted for. Triplicate dishes were seeded for each dose point. The dishes were returned to the incubator and irradiated 18–20 hours later at ambient temperature. X-rays were delivered from a General Electric Maximar unit operating at 220 kV potential and 15 mA with a half-value layer of 0.5 mm of copper. The X-ray dose rate was 80 rad/minute as measured by a condenser ionization chamber (Victoreen Instrument Div., Sheller-Globe Corp., Cleveland, Ohio). UV light (254 nm) exposures were done in a specially constructed irradiator consisting of a bank of five germicidal lamps. The UV dose rate was 0.35 J/m^2 as measured by a germicidal photometer (IL 254; International Light, Inc., Newburyport, Mass.).

After irradiation, the cultures were returned to the incubator, the medium was renewed at 5 days, and the cells were fixed and stained after 14 days. Macroscopic colonies of at least 50 cells were scored as survivors. A minimum of four dose points were used for each survival curve determination. The D_0 (the inverse of the slope) of the survival curve was determined from a least-square regression analysis of the individual data points. For UV survival curves, the D_0 was determined for the first (sensitive) component. The results presented in the text-figures and tables represent data pooled from three to five separate experiments.

Measurement of PLDR.—For measurements of the capacity of cells to repair potentially lethal damage, cultures were allowed to reach the confluent, density-inhibited phase of growth. The culture medium was then renewed daily for 3 days, and the experiment was performed on the 4th day. Replicate cultures were irradiated with a single dose of either X-ray or UV light and returned to the incubator. UV-irradiated cultures were overlaid with their own medium. At varying times thereafter, single dishes were removed, trypsinized, and seeded with fresh medium into three 100-mm petri dishes (Falcon Plastics) at low density to score for colony-forming ability as described above. An RF for X-ray and UV PLDR was calculated by the ratio of surviving colonies at the time of maximal repair (4–6 hr for X-ray PLDR and 24–30 hr for UV PLDR in normal controls) to surviving colonies at time 0.

Chromosomes from phytohemagglutinin-stimulated peripheral leukocytes from each Gardner's patient were analyzed with both C- and G-banding at the Cytogenetics Laboratory, Biotech Research Laboratories, Rockville, Md.

RESULTS

The sensitivities to X-ray and UV light irradiations and the ability to repair potentially lethal damage of cultured skin fibroblasts from the 2 Gardner's syndrome families were compared to those of 2 normal controls, 2 patients with nonfamilial colon cancer, and 1 patient each with AT and XP. A description of the non-Gardner's cell lines is presented in table 1.

The results for cultured skin fibroblasts from 4 clinically affected members of family 1 are outlined in table 2. All cell lines were found to be sensitive to the lethal effects of both X-ray and UV light irradiations. The X-ray D_0's were intermediate to those of the normal controls and sporadic colon cancer patients (D_0=135–160 rad) and AT patients (D_0=46 rad). Similarly, the UV D_0's for this family were intermediate to those of both controls ($D_0 \simeq 2.5$–3.0 J/m^2) and the XP patients ($D_0 \simeq 0.8$ J/m^2). A comparison of the mean D_0 of the 4 control cell lines with that of the 4 cell lines from family 1 by the generalized Wilcoxon test (*13*) showed a significant difference for both X-irradiation (148.8±11.1 vs. 107±6.7 rad; $P<0.01$) and UV light irradiation (2.83±0.24 vs. 1.35±0.13 J/m^2; $P<0.01$). Cell survival curves for both X-ray and UV light irradiations showed small and variable shoulders with the extrapolation numbers ranging from 1.0 to 1.8 (text-fig. 1).

To further investigate our observation of increased sensitivity to irradiation, we studied the PLDR in these cell lines. When normal human skin fibroblasts are irradiated with either X-ray or UV light while in the density-inhibited stationary phase of growth and later subcultured to a low density to stimulate cell proliferation, cell survival is enhanced (*14*). The maximum enhancement occurs within 6 hours for X-ray PLDR and within 24–30 hours for UV PLDR. AT cell lines are deficient in X-ray PLDR, and XP cell lines are deficient in UV PLDR (*6*).

As previously described by Little (*15*), PLDR is associated

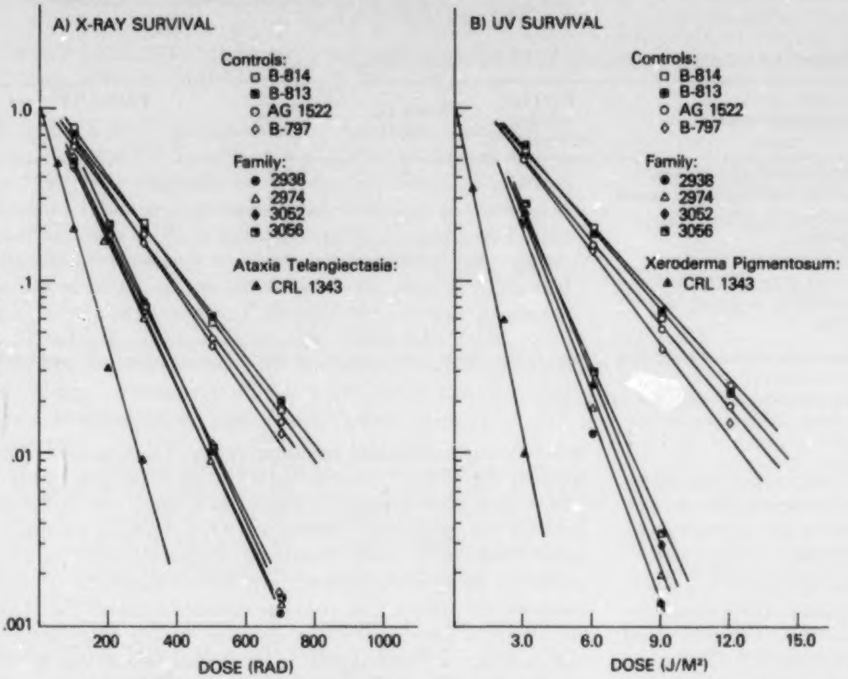
3056	16	Son of proband; asymptomatic; polyps only; total colectomy, no colon cancer	18	110	1.5	1.8	0.3

[a] Seven other family members affected with: colon cancer, colon polyps, and skin cysts (1 member), colon cancer and colon polyps (2 members), colon cancer (polyp status unknown) (1 member), and skin cysts (2 members).

[b] Calculated at 4–6 hr after X-ray irradiation and 24–30 hr after UV irradiation.

[c] Previously reported (*12*).



TEXT-FIGURE 1.—The X-ray A) and UV light B) survival curves of skin fibroblast lines from 4 members of family 1, 4 controls, and an AT (X-ray) or XP (UV) cell line.

with a change in the slope of the curve. An appropriate comparison of PLDR can be made by comparison at survival enhancement at similar levels of survival. To reduce the surviving cell population to 1% to quantitate PLDR, we used the following radiation doses: family 1 cell lines, 500 rad and 6.0 J/m^2; family 2 cell lines, normal control, and nonfamilial colon cancer lines, 700 rad and 12.0 J/m^2; an AT cell line, 300 rad and 12.0 J/m^2; and an XP cell line, 700 rad and 2.0 J/m^2.

We found no PLDR to UV light in any cell line (RF <1.0) from family 1 (text-fig. 2). A consistent delayed pattern of PLDR was noted to X-ray irradiation in these cell lines. A survival enhancement was not evident until 6–8 hours after irradiation, and the RF were lower than those of controls (RF=1.2–2.1 compared to 3.8–5.2) (text-fig. 2). The 2 nonfamilial colon cancer fibroblast lines showed a normal PLDR to both X-ray and UV irradiations.

Three members of family 2 have been studied of whom 2 are clinically affected with Gardner's syndrome. The patient from whom cell line 3090 was obtained appeared to be unaffected clinically but at age 17 might not have developed any phenotypic manifestations. However, all skin fibroblast lines tested in vitro showed a normal cell survival (D_0) and a normal pattern of PLDR after both X-ray and UV light irradiations (table 3).

Karyotyping of peripheral leukocytes was done on all Gardner's syndrome patients whose skin fibroblasts were tested. All leukocytes had a normal diploid pattern to C- and G-banding (Kinsella TJ, Little JB, Nove J, et al.: Unpublished data).

DISCUSSION

We have demonstrated a discordant response to the lethal effects of X-ray and far UV light in cultured skin fibroblasts in 2 families with Gardner's syndrome. In an earlier investigation of radiation sensitivity in 2 clinically affected members of family 1, increased sensitivity to X-ray and UV light irradiations and defective PLDR were postulated to represent a DNA repair defect responsible for the neoplastic and other manifestations of Gardner's syndrome (*12*). The normal response to both X-ray and UV light irradiations in the clinically affected members of family 2 does not support this hypothesis. The explanation for this difference in in vitro radiation sensitivity is unknown, and additional studies are needed. We cannot detect any difference in the phenotypic expression of Gardner's syndrome between families 1 and 2. Soft tissue benign tumors (lipomas, fibromas, and sebaceous cysts) occur throughout both family pedigrees. There were no reports in either family of skin carcinoma or of skin intolerance to therapeutic irradiation.

Increased sensitivity to X-irradiation of cultured skin fibroblasts has been found in other autosomal dominant diseases both with and without a cancer predisposition [familial retinoblastoma (*10*) and Huntington's chorea (*16*), respectively]. In retinoblastoma, there appears to be a difference in the in vitro radiosensitivity between patients with sporadic and hereditary retinoblastoma. These in vitro data support the clinical observation of an increase of secondary cancer (usually osteogenic sarcoma) within the radiation field for hereditary retinoblastoma (*17*). Further studies on radiosensitivity in some D-deletion retinoblastoma patients suggest a locus for radiosensitivity in the long arm of chromosome 13, adjacent to that for retinoblastoma (*19*). Theoretically, a patient with a deletion in the long arm of chromosome 13 encompassing both loci would be at the greatest risk of radiation-induced cancer. Chromosome analysis in both families affected with Gardner's syndrome revealed no chromosomal abnormalities.

Increased radiosensitivity is also reported in cultured skin fibroblasts (*16*) and in Epstein-Barr virus-transformed lymphocytes (*18*) from Huntington's chorea patients and some at-risk family members. Again, the radiosensitivity is postulated to reflect a defective DNA repair based on similar pathologic features of CNS neuronal degeneration found in another disorder of radiosensitivity, AT (*20*). No CNS degeneration occurs in patients with Gardner's syndrome, but in Turcot's syndrome, a presumed autosomal recessive polyposis disease, CNS tumors (usually gliomas) are a clinical manifestation (*21, 22*).

XP is the best characterized DNA repair-deficient human disease. Patients affected with this autosomal recessive disease develop sunlight-induced skin cancer with a frequency approximating 100% by age 20 (*11*). Cultured skin fibroblasts are sensitive to UV light irradiation and are usually unable to repair potentially lethal damage (*7*). A variable defect in the pyrimidine dimer excision repair pathway is demonstrated in most patients. However, cultured cells from some patients are proficient in excision repair but defective in postreplication repair (*23*). These cells also show a normal PLDR to UV light. This heterogeneity in in vitro testing of DNA repair of skin fibroblasts from XP patients may suggest a comparable explanation for the different findings in the 2 study families with Gardner's syndrome.

Danes and Krush (*24*) reported increased tetraploidy in short-term cultures that contain both skin epithelial cells and fibroblasts in 28 patients affected with Gardner's syndrome. In addition, tetraploidy was present in skin epithelial cell and fibroblast cultures in 19 of 50 family members at risk. Cultured skin fibroblasts alone did not show increased skin tetraploidy in affected patients or in family members at risk. However, another group failed to substantiate the usefulness of this short-term epithelial cell culture assay in detecting affected individuals with Gardner's syndrome (*25*).

Kopelvich and colleagues have extensively used skin fibroblast cultures to investigate a possible DNA repair defect in patients with polyposis syndromes that include Gardner's syndrome. They report several abnormalities in some skin fibroblast cultures from these polyposis patients, including increased susceptibility to viral transformation (*26*), defective organization of the fibroblast actin matrix (*27*), and malignant transformation through only a tumor promoter (*7*). The authors argue that skin fibroblasts from these polyposis patients are already initiated to carcinogenesis. The clinical phenotype of Gardner's syndrome includes benign and malignant soft tissue tumors to support this argument.

Colon epithelium cells from patients with Gardner's syndrome show increased tetraploidy (*28*) and abnormal growth kinetics by tritiated thymidine incorporation (*29*). At the present time, further in vitro testing is limited by the technical difficulty of establishing long-term bowel epithelium cultures.

In summary, the increased sensitivity of cultured skin fibroblasts to X-ray and UV light irradiations does not appear to be a consistent in vitro marker of gene carriers of Gardner's syndrome. However, the possibility should be considered that radiosensitivity segregates with a Gardner's syndrome gene in some affected families and is useful in identification of high-risk persons in those kindreds.

Systemic Administration of Human Leukocyte Interferon to Melanoma Patients. I. Effects on Natural Killer Function and Cell Populations[1,2,3]

Sidney H. Golub,[4] **Fred Dorey,**[5] **Dean Hara,**[4] **Donald L. Morton,**[4] *and* **Martyn W. Burk**[4,6]

ABSTRACT—Natural killer (NK) cytotoxicity was assessed against K562 targets in 14 melanoma patients who received daily im doses of human leukocyte interferon (IFN) for 42 consecutive days. The most common pattern of NK activity was a decline from pretreatment levels 1 day after initiation of treatment, followed by increasing cytotoxicity with peak activity at day 7 and a subsequent gradual decline to pretreatment levels during the remaining weeks of treatment. This pattern was particularly apparent in patients who received 3×10^6 or 9×10^6 U IFN/day, while patients who received 1×10^6 U IFN/day tended to lack the decline at day 1 and maintained the elevated NK activity past day 7. Changes in NK activity could not be related to changes in absolute lymphocyte counts; to proportions of cells bearing membrane receptors for sheep red blood cells, of cells bearing membrane receptors for erythrocyte-antibody-complement, or of cells bearing FCγ receptor; or to clinical response to IFN.—JNCI 1982; 68: 703–710.

Considerable interest has focused recently on the use of IFN as an antineoplastic agent in humans (*1–3*). Thus far, IFN has not been used extensively for patients with metastatic malignant melanoma. We are participating in a multiinstitutional trial sponsored by the American Cancer Society to investigate the possible therapeutic benefit of human leukocyte IFN (IFN-α) for the treatment of malignant melanoma. Clinical results of this trial will be reported separately. This report will focus on the effects of IFN on NK activity and cell surface markers. Systemic administration of IFN to cancer patients results in a marked increase in NK activity shortly after first administration (*4, 5*). We investigated the effect of daily doses of IFN given over a 42-day period. The purpose of these studies was to determine how long and at what level elevated NK activity could be maintained.

NK activity in these patients is of interest for several reasons. First, NK cells are cytotoxic to tumor cells and may contribute to the host defenses against the neoplastic disease. Whether the therapeutic benefits of IFN are due to elevated NK activity or to some other mechanism such as direct antineoplastic effects, is difficult to determine. However, NK activity is an easy and convenient means to measure the biologic activity of IFN. Thus measurement of NK activity in a systematic fashion following administration of IFN may prove useful in the adjustment of dosage and time schedules for the use of this agent.

MATERIALS AND METHODS

Patients.—Sixteen patients with metastatic malignant melanoma were entered into the study. Patients had metastases to subcutaneous tissues and/or lungs. The patients received daily doses of 1×10^6 U, 3×10^6 U, or 9×10^6 U IFN for 42 consecutive days. The IFN was human leukocyte IFN (IFN-α) provided by the American Cancer Society as part of a multiinstitutional trial. The patients were randomly assigned dosage, and the IFN was administered by im injection. Toxicity and therapeutic benefit is the subject of a separate report (*6*). The present report focuses solely on immunologic effects in the first 16 patients treated.

Preparation of PBL.—PBL were obtained daily for 2 days before initiation of IFN treatment, daily for 3 days after initiation of treatment, and weekly thereafter. PBL were prepared on standard Ficoll-Hypaque gradients and tested immediately after preparation. Samples were also cryopreserved as described previously (*7*) for future analysis. All results reported in this study utilized freshly prepared cells and not cryopreserved cells.

Cytotoxicity assay.—NK cytotoxicity was measured against K562 myeloid leukemia cells. In some experiments, additional targets were included. These included the human melanoma cell line UCLA-SO-M14 (henceforth termed "M14"), which is generally resistant to NK cytotoxicity in a 4-hour assay but is sensitive in long-term (>18 hr) cytotoxicity tests (*8*). We have also used M14 cells coated with rabbit anti-M14 IgG to measure ADCC. Also tested were L14 cells, an EBV-transformed B-lymphoblastoid cell line derived from the peripheral blood of the donor of the M14 line. For all cytotoxicity assays a microcytotoxicity ^{51}Cr release assay was used as described previously (*9*). E:T were 100:1, 50:1, 25:1, and 12.5:1 with all targets. Results are expressed as percent cytotoxicity calculated by the formula: Percent cytotoxicity=(cpm released in test−spontaneous release)/(total release−spontaneous release)×100. Spontaneous release was determined in the wells containing targets

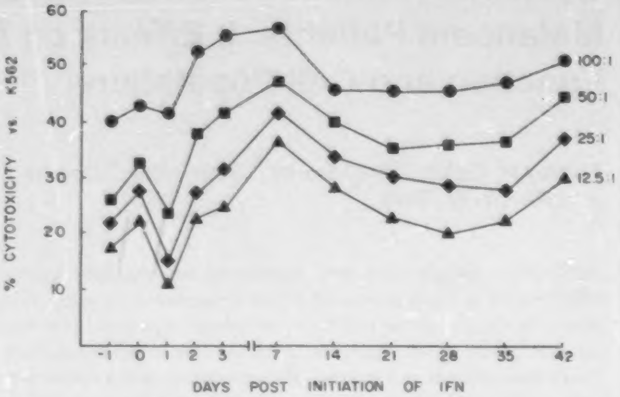
without added lymphocytes, and total release was calculated from wells containing targets and 5% Nonidet P40 detergent. All tests were performed in RPMI-1640 medium, supplemented with antibiotics and 10% pooled human AB serum. One lot of serum was used, and this lot had been screened and showed no activity in ADCC and no augmentation or diminution of NK cytotoxicity when compared to other serum supplements. Fetal bovine serum was not used because we had shown previously that it can induce NK-like cytotoxicity (*8*). To assure ourselves that the cytotoxicity assay was working properly each day, we thawed a sample of cryopreserved PBL from a single batch from 1 donor and tested it during each experiment. These data were used simply as a quality control on the cytotoxicity test and as a means of searching for systematic variations, such as those due to day of the week, in the assay system.

Cell surface markers.—Each patient's PBL samples were tested for the proportion of cells bearing the receptor for sheep RBC (rosette-forming cells) characteristic of T-cells, for the proportion of cells binding ox RBC coated with rabbit IgG to detect Fcγ receptor cells (EAγ rosette-forming cells), and for the proportion of cells binding sheep RBC coated with rabbit IgM and DBA/2 mouse complement to detect complement receptor cells (EAC rosette-forming cells). Total WBC counts and differentials were also performed. The technique of rosette formation and further details of the reagents used were detailed in (*10*). The healthy control donors were also tested sequentially for their proportion of cells bearing membrane receptors for EAγ (rosette-forming cells). Previous studies in this laboratory with both cancer patients and controls (*11–13*) showed no significant changes over time in the proportion of cells bearing membrane receptors for sheep RBC or EAC rosette-forming cells and therefore these assays were not repeated with this group of control donors.

RESULTS

Changes in NK Activity of IFN-Treated Patients and Controls

When all 14 IFN-treated patients were considered as a group, regardless of dose of IFN administered, a consistent pattern of increased cytotoxicity against K562 targets was seen. This pattern is shown in text-figure 1 for all four E:T tested. Typically, cytotoxicity declined after 24 hours of treatment, then increased steadily until day 7 of treatment, and then returned to pretreatment levels for the duration of treatment. This is illustrated with a representative patient in text-figure 2. This patient showed a striking increase in NK cytotoxicity against K562 targets during week 1 of treatment, then a decline toward pretreatment levels during the subsequent period of IFN treatment, and a further decline after treatment was completed. This pattern was seen at all four E:T tested; however, only the lowest ratio showing the greatest increase is shown in text-figure 2. Also illustrated in text-figure 2 is the small standard error for any single ^{51}Cr release assay. This pattern was followed by most of the individuals tested (*see* also table 2). At day 7, 81% of the patients had higher NK activity than at the pretreatment samplings ($P<0.01$; Wilcoxon rank sum test), whereas 56% were elevated at day 21.



TEXT-FIGURE 1.—NK cytotoxicity vs. K562 targets of 14 IFN-treated melanoma patients. Four E:T were tested. All results are the average percentages of cytotoxicity for the patients tested at each time point.

The different levels of NK activity at days 0 and 7 are shown in text-figure 3. The increased cytotoxicity is detected in parallel at all E:T tested. The fact that IFN-activated NK is detected equivalently at all ratios allowed us to reduce the data to a single number by simply averaging the percent lysis of all 4 doses. The results in text-figure 3 show that we are testing in the linear portion of the cytotoxicity dose-response curve at both days 0 and 7. Therefore, any of the four ratios could be used for analysis. We chose to incorporate all the information into one value by using the mean of the four ratios. This mean cytotoxicity was then compared to the pretreatment values (average of the mean cytotoxicity of days −1 and 0), and the net change in cytotoxicity was determined. This analysis confirmed our observation that peak cytotoxicity was expressed on day 7 of treatment (table 1). In fact, the day 7 values were the only statistically significant increases in NK cytotoxicity ($P<0.05$; both the paired *t*-test and Wilcoxon signed rank test).

In addition to the average change in NK activity, we determined the proportion of patients with elevated or

TEXT-FIGURE 3.—Average NK cytotoxicity for all 14 patients at days 0 and 7 of treatment. *Horizontal axis* also shows mean of four ratios. *Vertical bars* indicate standard error of the mean.

diminished NK activity at each time point. These data are shown in table 2 where the pretreatment values for 16 patients are listed. For clarity, NK results are shown only at selected posttreatment time points, but the proportion of patients increasing at each of the remaining time points is given at the bottom of table 2. This type of analysis confirms that increased NK activation is seen at day 7, inasmuch as 13 of 16 patients displayed increased NK activity on day 7 relative to pretreatment values ($P<0.01$; Wilcoxon signed rank test). In seven of nine sampling periods during IFN treatment, more than one-half of the patients showed increased NK activity. This would be a very unlikely finding if IFN had no effect on NK. The sole time point where less than one-half of the patients had increased NK activity was 24 hours after initiation of treatment (9 of 15 declined). This phenomenon is discussed below.

We examined the data to determine if any correlation existed between initial NK activity and subsequent NK activity. There was only a weak correlation between pretreatment values and the day 7 values ($r=0.35$; Pearson coefficient of correlation). The correlation between initial values and peak response was even less ($r=0.17$). Although we could not detect an obvious correlation between initial level and response to IFN, we cannot rule out the possibility that high initial values (e.g., patient #3, table 2) be precluded from a response because of some type of saturation of the NK system.

We also studied 4 healthy donors sequentially to determine what changes in NK activity might occur without IFN administration. These 4 donors were sampled at the same intervals as the patients and were studied concurrently with the patients. The results (table 1) show that the controls failed to demonstrate any increase in NK cytotoxicity. Thus a reasonable conclusion is that the consistent and significant

increase in NK activity in the patients was a result of the IFN treatment.

One interesting feature noted in both controls and patients was a decline in NK activity 24 hours after the first dose of IFN. The finding of such a decline in the immediate posttreatment period in the patients is not surprising; Kariniemi et al. (*14*) noted a similar phenomenon in IFN-treated healthy subjects. However, the similar decline in our untreated controls suggested that in some cases a decline in NK activity is unrelated to IFN treatment. We considered the possibility of a systematic error inherent in our NK assay. Because all patients and controls were entered into the study on a Monday (day −1), days 1 and 7 would always be on a Wednesday and Tuesday, respectively. If the test conditions tended to be poor on Wednesdays, we would see an artifactual decline in NK activity. Conversely, an increase in cytotoxicity at day 7 could be due to an abnormally sensitive NK assay system on Tuesdays. Considering the number of variables involved in the assay (e.g., lymphocyte preparation, tissue culture, and radiolabeling of K562), this possibility had to be considered. As part of this study, we had routinely tested aliquots of a single batch of cryopreserved PBL from 1 donor. We previously showed that cryopreserved PBL give highly reproducible results in immunologic assays (*7*) and retain activity in NK assays (*15*), although at a somewhat decreased level. When we analyzed these daily controls, no significant differences by day of the week were seen (table 3). Thus a systematic error in the NK assay was an unlikely explanation for either the decline in NK seen at day 1 or the increase at day 7. In fact, the increase at day 7 was particularly striking when compared to the results of other assays done on Tuesdays (days 0, 14, 21, 28, 35, and 42) in that this comparison has the fewest possible technical variables. We also arranged the control standard NK results according to the simultaneously tested patient samples. In this calculation, each time a patient was tested at a particular time point the simultaneous frozen standard result was also recorded at that time point. These results, also shown in table 3, indicate considerable stability in the NK assay. Whereas variation in the ^{51}Cr release assay on a day-to-day basis remains a problem with studies such as this, the assay appeared to have sufficient reproducibility to expose a strong trend such as the one seen in our group of patients.

NK Activity Against Targets Other Than K562

Preliminary studies have been initiated to determine if the IFN-augmented cytotoxicity is confined to K562 or can be detected against other targets as well. Thus far we have only studied 3 patients, all of whom showed marked increases against K562. However, when tested against the NK-resistant M14 melanoma target, none of the 3 patients showed any increased cytotoxicity after IFN treatment. Cytotoxicity, before and after IFN administration, never exceeded 5% lysis. One patient was also tested for ADCC against M14 targets coated with rabbit anti-M14 IgG. The activity of ADCC paralleled NK activity with an increase from 25% (E:T, 100:1) at day 0 to 45% at day 7. Therefore, the M14 targets were susceptible to lysis in ADCC, and activity of ADCC also appeared to respond to IFN treatment. The 3d patient was tested against an EBV-transformed B-cell line (L14) modestly susceptible to NK killing. Activity against the L14 increased from a pretreatment value of 7% to a peak of 47% during IFN treatment. Thus our preliminary results suggested that IFN-activated cytotoxicity can be detected against targets besides K562, such as L14 or IgG-coated M14, but not against all targets because untreated M14 cells remained resistant.

[a] Each sample was tested at four E:T and the results are expressed as the means of the four ratios. Results are expressed as the averages of these individual means.

Effect of Dose of IFN Administered on NK

NK activity was evaluated according to the dose of IFN administered to the patients. The results, expressed as net changes in mean percent cytotoxicity, are shown in table 4. Although the size of these groups was too small to justify meaningful statistical comparisons, some observations could be made. The lowest dose used (1×10^6 U IFN/day) was as effective in elevating NK activity as the higher doses (3×10^6 or 9×10^6 U IFN/day), and this low dose may even have been more effective in maintaining the elevated NK activity after week 1 of treatment. Of the 3 patients who failed to

show any increase in NK, 2 were treated with 9×10^6 U IFN/day and 1 was treated with 3×10^6 U IFN/day. In contrast, the higher doses seem more likely to induce a sharp drop in activity at 24 hours, followed by a distinct rise during week 1. Of the 5 patients who did not decline at day 1, 3 were treated with 1×10^6 U IFN/day and 2 received 3×10^6 U IFN/day. Therefore, the lowest dose of IFN used in this study appeared to be sufficient for maximal activation of NK. This, of course, does not mean that therapeutic effects will be similarly affected.

Although NK activity did not show an obvious IFN dose-dependent response, the decline in circulating leukocytes did (table 5). The leukopenic effects of IFN were most apparent with the higher doses administered. This suppression was confined to the granulocytes because the proportion of lymphocytes rose during treatment (table 5), and absolute lymphocyte counts were not significantly affected (table 5; text-fig. 4).

Effect of Time Interval Between IFN Administration and Sampling on NK Activity

Other studies in humans have indicated that peak NK activity is detected 12–48 hours after first administration of IFN (*4, 5*). We had intended to do all sampling at 24 hours after the previous IFN dose, and this procedure was followed during the first 3 days while the patients were hospitalized (days 1, 2, and 3 of treatment). For subsequent treatments, the patients administered the IFN themselves. In many cases, the patients chose to administer the agent the morning before the clinic visit. Thus in about one-half of the samples the IFN was administered from 1 to 5 hours before PBL samples were obtained, whereas in the others the IFN was given 12–24 hours before sampling. We have compared the cytotoxicity according to this interval, and the results are given in text-figure 5. No statistically significant differences could be detected between the shorter or longer time intervals at any of the four treatment points analyzed. Later treatment points (days 35 and 42) had too few samples with the short intervals to allow for comparison, and the early treatment points (days 1, 2, and 3) were uniformly tested at 24 hours post IFN. Thus we could not find any substantial difference in NK activity during the later treatment periods (1–4 wk of treatment) between those who received IFN less than 5 or more than 12 hours before sampling. However, in three of the four time points in text-figure 5 (days 7, 14, and 28), the longer interval results were higher. Therefore, we may have slightly underestimated the NK activity in some patients. All patients are now carefully instructed to administer the IFN at the designated time of day, and further studies will have greater uniformity in this respect. Irrespective of time intervals between dose and sampling, the longer periods of IFN treatment (14–28 days) displayed lower NK activity than did the peak period (7 days). Therefore, it is unlikely that the later period of declining NK is associated with a change in the kinetics of NK activation. We also obtained repetitive samples from patients late in the course of treatment when NK activity had declined. These samples, obtained over a 12-hour period following the next dose of IFN, also remained low in NK activity (data not shown).

TABLE 5.—*Dose effect of IFN on WBC counts and percent lymphocytes*

Day of treatment	Average total WBC (average percent lymphocytes)[a] at IFN dose of:

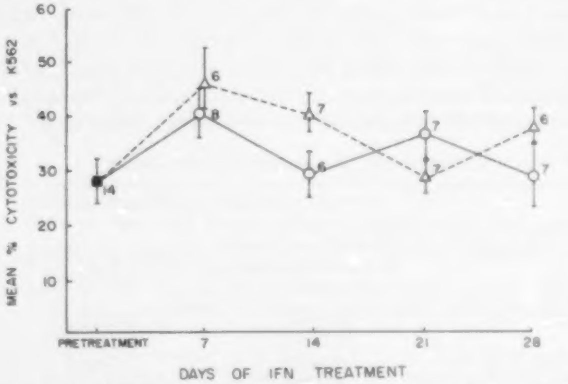
Changes in Cell Populations During IFN Treatment

We have monitored the ability of PBL from these patients to form sheep RBC, EAγ, and EAC rosettes during IFN



TEXT-FIGURE 5.—Effect on NK activity of time interval between IFN administration and sampling. *Vertical axis* shows mean of four ratios averaged for group of patients. Samples drawn 12–24 hr after previous IFN dose (△—△) are compared to samples drawn 1–5 hr after previous dose (○—○). *Vertical bars* indicate standard error of the mean. *Numbers adjacent to symbols* indicate number of patients tested.

treatment. The results are shown in text-figure 4. No substantial changes in the ability to form rosettes were associated with IFN treatment. Thus changes in NK activity cannot be ascribed to changes in proportions of T-cells, of complement receptor cells, or of cells bearing Fcγ receptors. Although the average rosette values did not change, possibly separate subgroups of patients were simultaneously rising and declining. However, examination of the data from the individual patients showed that most were quite stable. No characteristic patterns could be identified for any of the subgroups separated on the basis of IFN dose or clinical response. Similar stable results (data not shown) were obtained with sequential tests for EAγ (rosette-forming cells) with the 4 healthy controls.

Also shown in text-figure 4 is the absolute lymphocyte counts. Except for a brief period of variability immediately after the start of IFN treatment, total lymphocyte numbers were also remarkably stable. Thus changes in NK activity on a per-cell basis can also be taken as estimates of total NK activity. No noteworthy changes in lymphocyte numbers or populations (as measured by these three rosette assays) could be detected during IFN treatment.

Correlation of NK Activity to Clinical Response

Five patients (2 given high dose; 2, intermediate; 1, low dose) were considered to have had some benefit from IFN therapy as shown by either regression of established lesions or stabilization of previously rapidly growing tumors. Conversely, 4 patients (1 given high dose; 1, intermediate; 2, low dose) had more rapid tumor growth while on treatment. NK activity for these 2 subgroups is compared in table 6. Both groups responded to IFN treatment with equivalent increases in average NK cytotoxicity. All 4 patients who did poorly and 4 of 5 patients who did well had NK activity elevated at day 7 when compared to NK activity at day 0. The only discernible difference between these groups is the somewhat lower initial pretreatment cytotoxicity for the patients who had continued rapid disease progression ("nonresponders"). The 2 groups were comparable in other pretreatment values; the nonresponders had an average absolute lymphocyte count of 1,395/mm^3, 60.5% sheep RBC rosettes, and 19% EAγ rosettes, whereas the "responders" had pretreatment values of 1,316 lymphocytes/mm^3, 53.8% sheep RBC rosettes, and 16.8% EAγ rosettes. Whether pretreatment NK cytotoxicity will be a useful discriminant for predicting who will respond to IFN therapy obviously cannot be determined from this small sampling, although it does appear to warrant further examination. Even those patients who had very poor clinical responses to IFN did demonstrate increased NK responses.

DISCUSSION

We aimed to define the parameters of changes in NK activity in a relatively homogeneous patient group treated with human leukocyte IFN. Our results indicate that systemic administration of an IFN-containing preparation regularly and reproducibly increased NK activity of PBL. There are several features of the pattern of NK cytotoxicity in these patients that may help to define some of the biologic properties of these agents. The general pattern we observed was a transient decline at 24 hours, followed by a gradual increase until peak cytotoxicity is reached about day 7 of treatment. Subsequently, NK activity tended to decline toward pretreatment values.

Our conclusion as to the pattern of NK response is based on two separate types of statistical analysis. We compared the mean response of all patients at each time point to their mean pretreatment response by the paired *t*-test (table 1). This analysis would smooth out some of the variation inherent in any repetitive testing of individuals and should provide a clearer picture of the underlying kinetics of the response to IFN. It will also provide an estimate of the magnitude of change. We also analyzed for the proportion of patients who increased at each time point over their individual pretreatment base-line values by the Wilcoxon rank sum test (table 1). This type of analysis is less sensitive to a few extreme responses. However, it does not provide an estimate of the magnitude of the changes. Both types of analysis, as well as inspection of each patient's results, lead to the conclusion that a common pattern of NK responses exists in most of these patients.

The initial decline at 24 hours following IFN treatment has also been described by Kariniemi et al. (*14*) in normal volunteers who received IFN and by Einhorn et al. (*16*) at 6 hours following treatment in cancer patients. Some caution is required in interpreting this decline because we observed a similar decline in normal controls who did not receive IFN (table 1). Since this decline in NK activity could not be related to any systematic error in the NK assay (table 2), it may be related to repetitive venipuncture or other hard-to-define variables. Our observation that the decline in NK activity at 24 hours was most pronounced among the patients who received the highest IFN doses does indicate that at least a component of this decline may be a real consequence of IFN treatment. The reasons for this decline are unclear, although redistribution of NK cells seems the best available explanation (*14*).

Time of peak NK activity was 7 days following initiation of treatment in our study, which is later than in other published observations of NK activity in IFN-treated cancer patients. Einhorn et al. (*4*), using single doses or daily doses (*16*) of 3×10^6 U IFN, found peak NK activity at 12–24 hours after initiation of IFN treatment. Similar results were reported by Huddlestone et al. (*5*) in a small series of patients who received 10×10^6 U IFN, whereas Kariniemi et al. (*14*) found no augmentation within 5 days in normal volunteers who received 3×10^6 U. Differences in purity of the IFN used and differences in the immune status of the individuals treated probably cause some of the differences in kinetics among the various studies. Our results are most similar to the results in normal healthy subjects (*14*), except that we find a significant increase in NK activity. The similarity of our results and those in IFN-treated healthy subjects probably reflects the relatively small impairment in immune status in stage III melanoma patients (*17*). All in vivo studies show agreement that systemic administration results in a less rapid increase in NK activity than can be achieved by the in vitro exposure of lymphocytes to IFN (*18*). This implies the existence of control mechanisms in addition to the direct interaction of IFN with NK cells, and this possibility is addressed in (*19*).

We observed that continued daily doses of IFN generally failed to maintain NK cytotoxicity at the elevated level after peak activity was reached on day 7 of treatment. This return to pretreatment NK activity is not due to any detectable change in kinetics of response, because samples obtained 1–5 hours or 12–24 hours after IFN administration were equivalently low in cytotoxicity (text-fig. 5). This observation is somewhat different than the results of Einhorn et al. (*16*), who found that long-term daily administration of 3×10^6 U IFN resulted in continued elevated NK activity. We observed a similar maintenance of high NK cytotoxicity in our lowest-dose group (1×10^6 U/day) (table 3), and therefore small differences in purity or dosage may explain this discrepancy. Also, we evaluated the patients weekly for 7 weeks and did note a slight but statistically insignificant increase in week 7 of treatment, whereas Einhorn et al. (*16*) measured NK activity at 3-month intervals. Thus a pattern of declining NK in the immediate weeks following initiation of treatment with a return to elevated NK activity upon longer treatment would be consistent with both sets of results. This finding suggests a cycling of NK activity, which may indicate an effect of IFN on NK precursors. This possibility is discussed more thoroughly in (*19*).

Our results (text-fig. 5) indicate that IFN administration is not associated with any significant change in the proportion of cells bearing the membrane receptors for sheep RBC or EAC or of cells bearing Fcγ receptors (EAγ). Thus changes in NK activity cannot be associated with any redistribution of cell types as measured with these assays. The lack of change in proportion of Fcγ receptor cells is interesting in light of observations on increased expression of Fcγ receptors when cells are treated in vitro with IFN (*20, 21*). Although it is possible that the Fcγ receptor cells are expressing more receptors per cell in the IFN-treated patients, both studies cited above showed enhanced Fcγ receptor expression by increases in the proportion of cells bearing membrane receptors for EAγ. Our failure to detect any such change in these patients again points out the difference between the in vitro and in vivo immunologic effects of IFN.

Finally, we had hoped that the effects of IFN on NK activity would be a useful indicator of those patients obtaining clinical benefit from this agent. This does not appear to be the case, because both clinical responders and nonresponders showed equivalent increases in NK activity (table 6). However, those patients who had some clinical benefit from IFN did appear to have higher pretreatment levels of NK activity. This may be related to a greater tumor burden in the poor responders; NK activity has been reported to be suppressed in patients with large tumor burdens (*22, 23*). A larger series of patients will have to be studied to determine if pretreatment NK level will predict response to IFN treatment with any accuracy. The variability of both NK assays and of NK activity in the population probably will preclude actually selecting patients for treatment on this basis, but further investigation in this area may help determine the basis of IFN action in the cancer patient.

Systemic Administration of Human Leukocyte Interferon to Melanoma Patients. II. Cellular Events Associated With Changes in Natural Killer Cytotoxicity[1,2,3]

Sidney H. Golub,[4] Paula D'Amore,[4,5] *and* Marcia Rainey,[4,6]

ABSTRACT—Treatment of patients with malignant melanoma with daily doses of human leukocyte interferon (IFN) resulted in natural killer (NK) cytotoxicity that increased during the 1st week of treatment and subsequently declined to pretreatment levels despite continued IFN administration; events involved in these changes were examined. The increased cytotoxicity was associated with an increased number of cells able to bind K562 targets and an increased proportion of cells able to mediate cytolysis of K562 targets. The period of increasing NK activity was also associated with an increased ability to generate in vitro cytotoxic effectors against K562 targets by stimulation with allogeneic lymphoblastoid cells. The responding cells in this system were depleted of NK activity by adherence to immune complexes. These results suggested that increased NK activity during week 1 of in vivo treatment was associated with augmentation of the development of NK cells from noncytotoxic precursors in addition to direct effects on NK cells. In contrast, the decline in NK activity appeared to be primarily a direct effect on NK cells, because these cells could no longer be augmented in vitro by additional IFN. The refractory state to IFN augmentation of cytotoxicity was limited to the period of IFN treatment in vivo, and responsiveness to IFN was promptly regained upon cessation of treatment. No evidence for the development of suppressor cells of NK effector function could be obtained.—JNCI 1982; 68:711–717.

The preceding paper in this series (*1*) described a consistent pattern of changes in NK activity after the systemic administration of human leukocyte IFN to patients with metastatic malignant melanoma. The administration of IFN is associated with an increase in circulating NK activity, which usually peaks by day 7 of continuous treatment. After the achievement of elevated levels of NK cytotoxicity, patients tend to display declining NK activity despite continued treatment with IFN. In the studies reported in this paper, we have addressed two questions: *a*) What are the events associated with the increase in NK activity early during IFN treatment and *b*) what are the events associated with the subsequent decline in NK cytotoxicity?

Increases in NK cytotoxicity either could be the result of direct activation of mature NK cells by IFN (*2, 3*) or could include activation of precursor cells not previously capable of mediating cytolysis. We have attempted to address this question by an analysis of the target-binding cells during the course of IFN treatment and by analyzing the ability of NK-depleted cell populations to generate anti-K562 killer cells.

Several possible explanations for the decline in NK cytotoxicity following IFN treatment can be envisioned. The pool of precursor cells, presumably located in the bone marrow, may become exhausted; the activated NK cells may redistribute from the circulating compartment and therefore may no longer be detectable in the peripheral blood; the cells may become refractory to further IFN stimulation; or suppressive mechanisms, including suppressor cells, may become activated. The first two possibilities, redistribution of cells or exhaustion of bone marrow precursors, are difficult to test in the human and therefore we have concentrated on the other two possibilities: resistance to further IFN activation and development of suppressor cells.

Our results thus far indicate that the early phases of increased NK activity following IFN treatment are associated with increases in both the number of cells able to mediate NK lysis and the number of TBC. Furthermore, IFN treatment also appears to be associated with an augmented response to alloantigen-induced NK activity. Thus our data are consistent with increases in both NK precursors and mature NK cells following IFN treatment. The subsequent decline in NK activity is associated with increased resistance of cells to in vitro activation by IFN. However, we could find no evidence for the development of suppressor cells to NK activity.

MATERIALS AND METHODS

Preparation of lymphocyte samples.—The patient population tested was described in the previous paper in this series (*1*). PBL samples were prepared by standard Ficoll-Hypaque density gradient centrifugation procedures and were cryopreserved as previously described (*4*). Cryopreserved cells were used, in general, when we subjected cells to identical manipulations and the cells were drawn from the same patient at different time points during treatment. Cryopreserved cells were used for all studies in this report except the sequential analysis of TBC and of cytotoxic cells in the single cell assay and in some of the in vitro activation with IFN experiments. Previous studies in our laboratory have shown that cryopreserved cells retain NK cytotoxicity, al-

though it is uniformly at a predictably diminished level of activity (*5*).

Cytotoxicity assays.—NK cytotoxicity was measured against K562 targets by the standard ^{51}Cr release assay described in the preceding paper. With freshly prepared PBL, the assay was tested at four serial dilutions yielding E:T from 100:1 to 12.5:1, and the results were expressed as the means of all four ratios. With cryopreserved lymphocytes, cell recovery generally allowed testing only at the 100:1 ratio. In addition to the ^{51}Cr release assay, we have used the single cell binding and lysis assay developed by Grimm and Bonavida (*6*) and modified for human NK assessment by Targan and Dorey (*3*). Equal numbers (2.5×10^5) of PBL and target cells were mixed in 0.1 ml, incubated for 10 minutes at 37°C, and centrifuged for 10 minutes at 1,200×*g*. Warm (37°C) 1% agarose solution (100 µl) was added to each tube and gently mixed with the cells. The cell suspension was then spread onto a glass slide coated with 2% agar. When the agarose had solidified, one set of slides was read for binding cells, and another set was incubated for 3 hours at 37°C. This set was then stained for 6 minutes in trypan blue, washed in RPMI-1640 medium for 10 minutes, and fixed in Formalin for scoring of dead targets. Each set was done in duplicate, and 300 PBL were scored on each slide. Results never varied more than 1% from one slide to its duplicate. For the studies on the characteristics of the killer cells, at least 100 binding cells were scored in the lysis assay. Results in this assay were expressed as either percentage of PBL binding K562 in the binding assay or percentage of total PBL with bound and dead K562 as determined by trypan blue staining in the lysis assay.

The human leukocyte IFN (IFN-α) used in vitro was generously provided by Dr. M. Krim, Sloan Kettering Institute, and was used in vitro at a dose of 100 U/ml. Cells were pretreated for 60 minutes in 1 ml and washed prior to testing. Indomethacin (Sigma Chemical Co., St. Louis, Mo.) was used at 1×10^{-5} *M* and was included in the cytotoxicity assay for the 4-hour duration of the test.

Induction of NK-like cytotoxicity by stimulation with allogeneic lymphoblastoid cell line cells.—PBL were depleted of anti-K562 cytotoxic NK cells by passage over monolayers of EAγ according to the method of Kedar et al. (*7*). These monolayers were constructed with the use of sheep RBC and rabbit anti-sheep RBC IgG. The NK-depleted PBL were then assayed in MLC–CML assays as previously described (*5*). The cells were stimulated in vitro with irradiated allogeneic lymphoblastoid cell line cells, and separate MicroTest plates were assayed for [^{3}H]thymidine incorporation (MLC) and cytotoxicity against K562 targets (CML) after 6 days of incubation. The efficacy of the monolayers of EAγ was routinely checked by loss of activity in NK assays and depletion of EAγ (rosette-forming cells).

Depletion of adherent cells.—Adherent cells were depleted by passage over Sephadex G10 columns. PBL, 5–10 million, were passed over a G10 1-ml column (Pharmacia Fine Chemicals, Piscataway, N.J.) in a 5-ml disposable sterile syringe. The cells were allowed to incubate for 30 minutes on the beads before elution with 10 volumes of media. Efficacy of removal of adherent cells was confirmed by loss of cells staining for nonspecific esterase. Passage of PBL over nylon fiber columns was accomplished by the same technique with the use of columns packed with 100 mg of scrubbed nylon fiber (Fenwal Laboratories, Deerfield, Ill.).

RESULTS

Quantitation of TBC and NK Cells

We analyzed 4 patients with repeated assays of the number of K562 binding cells and K562 killing cells in the single cell assay system. The results for binding cells are seen in text-figure 1, and the results for lytic cells are shown in text-figure 2. Both results were given as the proportion of cells either binding or killing when compared to total PBL. Both binders and killers increased early during IFN treatment. Peak activity was found during week 1, usually at day 7, and closely paralleled the increased activity noted in the ^{51}Cr release assay, as described in the previous paper of this series (*1*).

After the achievement of peak levels of TBC or killer cells, the proportion of cells active in both these assays declined despite continued administration of IFN. The proportion of binding and killing cells after peak activity returned toward pretreatment levels but remained slightly elevated. This was also consistent with the ^{51}Cr release results as detailed in tables 1 and 2 in the previous paper in this series (*1*).

Some of the characteristics of the binding and killing cells are illustrated in table 1 in this paper. In these studies, cryopreserved PBL were used from an IFN-treated patient who showed a typical pattern of NK activity in ^{51}Cr release assays against K562, with peak activity on day 7. In contrast to results with the other 4 patients (text-fig. 1), no appreciable increase in K562 binding cells was seen after IFN treatment with this patient. However, the proportion of lytic cells approximately doubled in the samples drawn 2 or 7 days after the initiation of IFN treatment and then declined to below the pretreatment value after 35 days of treatment. Binding and killing cells were also assessed with the NK-resistant M14 melanoma targets. These targets have been shown to be resistant to lysis by either normal or IFN-

activated NK cells. Although as many M14 binders as K562 binders could be detected, the proportion of M14 killers was consistently very low both before and during IFN treatment. Thus the increased cytotoxicity appeared to be limited to NK-sensitive targets.

Depletion of the Fcγ receptor cells on EAγ monolayers resulted in a 60%- to 90%-depletion of EAγ rosette-forming cells. While this procedure resulted in only a partial depletion of K562 or M14 binding cells, it did substantially reduce the proportion of lytic cells. Approximately 80% of the killer cells were removed by passage over EAγ monolayers. Thus effectors obtained either before or during IFN treatment were predominantly Fcγ receptor-bearing cells. However, a population of Fcγ receptor-negative, nonlytic target-binding cells could also be detected. Passage of the PBL over nylon fiber columns to deplete B-cells and monocytes resulted in an enrichment for both binders and killers (table 1). In this case, we did observe the more typical increase in K562 binders early during IFN treatment and a subsequent decline. The increase in binders was accompanied by a parallel increase in the proportion of binders that killed the targets. The fact that the proportion of K562 binding and killing cells increased in day 2 and day 7 nylon nonadherent cells indicated that this elevation was not simply due to increased "stickiness" of cells from IFN-treated patients. Similarly, the lack of change in M14 binders argues against any nonspecific surface change. Also, nylon fiber fractionation reduced the proportion of Fcγ receptor cells while increasing NK activity. Presumably, NK inactive monocytes were removed on the columns.

In Vitro Generation of NK-Like Cytotoxicity From PBL of IFN-Treated Patients

Because the TBC data indicated an increase in the number of TBC after the initiation of IFN treatment, we considered the possibility that IFN treatment increases the number of NK precursors in the peripheral blood. To determine if there is any increase in the number or activity of NK inactive precursors of NK cells during IFN treatment, we attempted to generate NK activity in vitro. Cryopreserved PBL from various points during treatment were depleted of NK activity by passage over EAγ monolayers. The nonadherent cells were then stimulated in Microwell plates with allogeneic lymphoblastoid cell line cells. After 6 days of culture, sets of Microwell plates were assayed for proliferation and other sets were assayed for cytotoxic activity against K562 targets. The results of a representative experiment of this type are given in text-figure 3. The ability to generate NK activity in vitro shows a similar time course as the original NK activity as detected in the peripheral blood. No differences in proliferative activity were observed at any point during treatment, although differences were detected in cytotoxicity. Nonstimulated control PBL showed no cytotoxicity. In four such series of experiments with the use of PBL from 4 IFN-treated patients, increased anti-K562 cy-

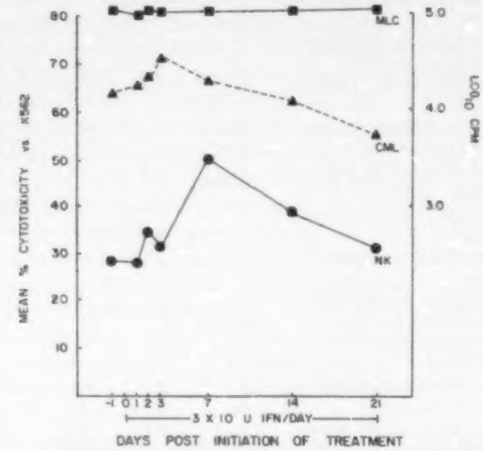
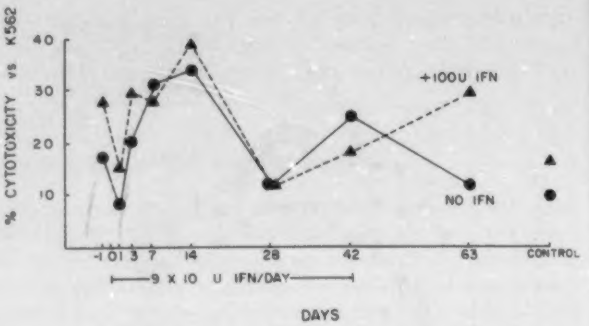
totoxicity could be generated from PBL drawn at the time of peak NK activity (2 patients) or at times just preceding peak NK activity (2 patients, including the one in text-fig. 3). These data supported, although did not directly prove, the concept that IFN treatment is associated with increase in NK precursors.

Effect of In Vitro Addition of IFN to PBL From IFN-Treated Patients

We next considered the possible explanations for a decline in NK activity following the achievement of peak levels of NK activity. One possibility is that the mature NK cells, or other IFN-responsive cells, become refractory to further IFN activation. We have examined this by comparing PBL from various time points during treatment for NK activity with and without the addition of a 60-minute pretreatment with 100 U IFN. Results for a typical experiment of this type are shown in text-figure 4, where cryopreserved PBL from 1 patient was tested in simultaneous assays with and without pretreatment with IFN. In this patient, IFN augmented anti-K562 NK activity of PBL obtained before treatment, early during treatment, or after the termination of treatment. In contrast, samples obtained from the period of peak NK activity through most of the rest of the treatment period were unresponsive to IFN. Similar results have been obtained with freshly prepared PBL tested with and without IFN in each repetitive test.

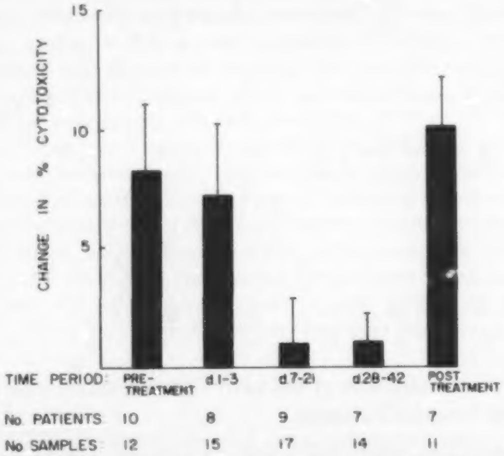


Text-figure 3.—NK and MLC–CML responses of PBL from patient #2. PBL were drawn at various times during treatment with 3×10^6 U IFN/day and were tested for NK activity. Cryopreserved samples were then depleted of Fcγ receptor cells and stimulated for 6 days in vitro with irradiated allogeneic lymphoblasts. One set of wells were assayed for [^{3}H] thymidine incorporation, and results are expressed as $\log_{10}$ cpm/1×10^5 PBL (*right vertical axis*) and are designated MLC. Other Microwell plates were assayed for cytotoxicity vs. K562 (CML). Both CML and NK results are mean cytotoxicity percentages of four E:T (*left vertical axis*). Cytotoxicity of Fcγ-depleted cells (without stimulation) did not exceed 1% for any sample at the highest of the four E:T.



Text-figure 4.—NK, with and without IFN pretreatment, of PBL from IFN-treated patient #1. Results are mean cytotoxicity percentages of four E:T (*vertical axis*) of PBL drawn at various times during treatment (*horizontal axis*). Control indicates PBL from a healthy donor. Cells were tested after incubation for 60 min in media with no IFN or 100 U IFN.

The results with 10 patients tested with 100 U IFN in vitro are summarized in text-figure 5. The results were expressed as average increase in cytotoxicity associated with pretreatment with IFN (percent cytotoxicity in presence of IFN minus percent cytotoxicity in absence of IFN). The results were accumulated into five time periods. The first was the pretreatment period, followed by three treatment periods comprising: the first three samplings (days 1, 2, and 3), the next three sampling periods during treatment (days 7, 14, and 21), and the last three treatment periods (days 28, 35, and 42). The final samplings were those after termination of treatment. When summarized in this fashion, it was apparent that pretreatment samples were regularly associated with increased NK activity with an average increase of 8.4%. Results from the earliest time periods were quite similar (average increase, 7.1%), but the response to IFN markedly diminished in subsequent samplings (<1% average increase). However, when the patients completed the course of IFN treatment, responsiveness in vitro to IFN activation of NK activity returned (average increase, 9.7%). The effect of time on in vitro response to IFN was statistically significant as determined by analysis of variance ($P<0.05$). Also, in vitro activation by IFN was statistically significant for the entire group of 69 lymphocyte samples tested from



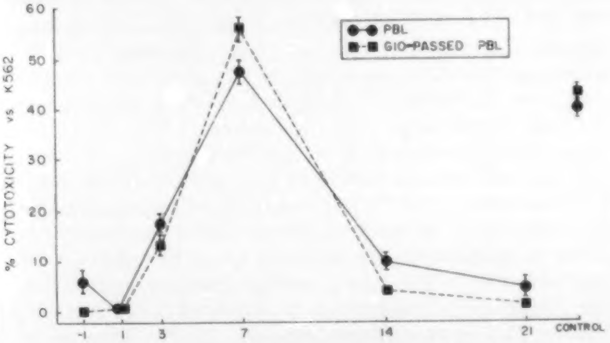
Text-figure 5.—Summary of in vitro IFN activation of NK. Results are cytotoxicity changes calculated as percent cytotoxicity with IFN − percent cytotoxicity without IFN. Results are averaged within time periods according to the number of patients, rather than number of samples, tested. *Vertical bars* indicate standard error. Days, d.

these patients ($P<0.01$; paired t-test). This simply indicated that our IFN was active for in vitro augmentation of NK cytotoxicity. We also tried treatment with IFN dosages of 10, 333, or 1,000 U and pretreatment periods of 24 hours. Neither different IFN dosages nor longer treatment could induce greater NK activity from PBL drawn late in the course of IFN treatment (data not shown). Thus these results showed that lymphocytes from the period of peak NK cytotoxicity through subsequent declining NK cytotoxicity were less responsive to IFN in vitro for the development of increased NK activity. The response returned to normal, or even above normal, levels following termination of IFN treatment.

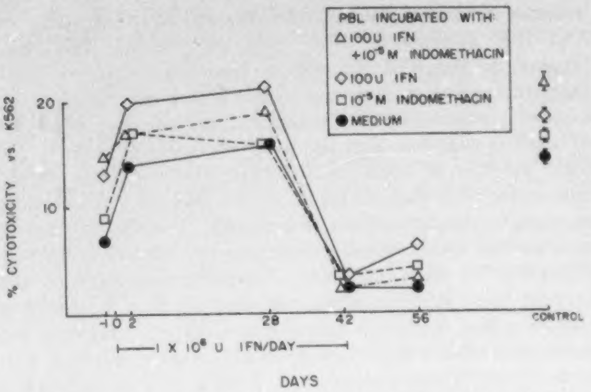
Lack of Adherent Suppressor Cells for NK Effector Function

We considered the possibility that declining NK activity was due to an adherent suppressor cell, particularly a prostaglandin-secreting suppressor cell. To examine this possibility, we tested PBL for cytotoxicity before and after removal of adherent cells by passage over Sephadex G10 columns. The results of a typical experiment are given in text-figure 6. Removal of G10-adherent cells had a slight enhancing effect on most PBL samples from normal donors, as illustrated with the control donor tested simultaneously with the patient samples in text-figure 7. However, removal of G10-adherent cells from the patient's PBL did not restore NK activity in PBL samples drawn past the peak of in vivo induced NK activity.

An alternative approach to searching for an adherent suppressor cell is shown in text-figure 7. In these experiments, 1×10^{-5} *M* indomethacin was added to abrogate the synthesis of prostaglandins. As shown in text-figure 7, indomethacin had a slight enhancing effect on NK activity of either the control lymphocytes or the IFN-treated patient lymphocytes. However, neither indomethacin alone nor indomethacin and IFN restored activity from postpeak low NK samples. This was best illustrated with the day 42 sample (text-fig. 7) where activity had declined to below pretreatment levels and could not be restored with IFN, indomethacin, or a mixture of IFN and indomethacin. These results, in combination with the G10 column fractionation experiments, failed to provide any evidence for a G10-adherent, indomethacin-sensitive suppressor cell contributing to the decline in NK activity during later periods of IFN systemic treatment.



Text-figure 6.—Effect of passage of PBL over G10 columns on NK cytotoxicity. PBL were drawn from patient #11 (3×10^6 U IFN/day). PBL and G10-passed PBL were tested at 100:1 vs. K562 (*vertical axis*), as were identically treated PBL from a healthy control donor. *Vertical bars* indicate standard error of the mean.



Text-figure 7.—Effect of IFN, indomethacin, or IFN + indomethacin on NK of PBL from patient #10 (1×10^6 U IFN/day). For clarity, standard errors are given only with PBL from healthy control donor. *Vertical bars* indicate standard error of the mean.

DISCUSSION

We studied the events involved in the increasing NK cytotoxicity noted during week 1 of treatment of patients with human leukocyte IFN and the events involved in the subsequent decline in NK activity despite continued IFN treatment.

In vitro treatment of lymphocytes with IFN requires only a short period of treatment to augment NK cytotoxicity (*8*, *9*), whereas in vivo treatment of patients results in increases of NK cytotoxicity, which are detectable only after 2–7 days after initiation of treatment. Since im injection of leukocyte IFN results in detectable circulating levels within hours after administration (*10*), one would expect increased NK cytotoxicity promptly after initiation of IFN therapy if direct interaction between IFN and NK cells was the sole mechanism involved in augmenting cytotoxicity. Instead, the delayed time course of increased NK cytotoxicity in these patients suggested an increase in the development of NK cells from noncytotoxic precursors. To test this possibility, we examined the proportion of cells binding to K562 targets. Sequential studies of 4 patients clearly indicated an increased number of TBC shortly after the initiation of IFN treatment (text-fig. 1). Furthermore, there is also a parallel increase in the proportion of lymphoid cells that are actually mediating cytolysis of the K562 targets (text-fig. 2; table 1). If we assume that the lineage of NK cells involves differentiation of nonbinding, noncytotoxic precursors into binding cells ("pre-NK" cells) and then into mature binding and killing NK cells, our data would be consistent with the construct of an increase in the number of pre-NK cells and an increase in the development throughout this pathway, that is, an increase in the number of pre-NK cells and an increase in mature NK cells. In vitro studies have indicated that IFN appears to affect primarily mature NK cells, because depletion of NK cells on immune complexes abrogates the ability to augment cytotoxicity with IFN (*2*) and in vitro treatment with IFN does not increase the proportion of binding cells but only the proportion of killing cells and their kinetics of lysis (*3*, *9*). Our results are in partial agreement with those of the in vitro studies; we observed an increase in the proportion of lytic cells (text-fig. 2), and all activity was localized to Fcγ receptor-bearing cells (table 1). However, we also observed a consistent increase in the proportion of K562 binding cells (text-fig. 1). This increase indicates that there is a substantial difference between the short-term effects of IFN on NK cells in vitro and the long-term effects of repeated treatment with IFN in vivo. Thus the in vitro models appear to be quite useful for the examination of the effects of IFN on mature NK cells but fail to reveal the possible effects of IFN on precursors of NK cells. The increase in TBC found after systemic administration of IFN argued for an increased recruitment of NK cells from a noncytotoxic pool. These results are somewhat in contrast to the failure to find increased binding cells in mice treated with tilorone, an IFN inducer (*11*). Possibly, IFN and IFN inducers do not have identical effects on the NK system.

Since we do not have reliable phenotypic or functional markers for noncytotoxic, nonbinding NK precursors, it is difficult to test the hypothesis generated from these results that IFN administration promotes differentiation into NK cells. In an attempt to deal with this question, we turned to the in vitro generation of "NK-like" cytotoxicity. This type of cytotoxicity, which mimics NK cytotoxicity in specificity, can be generated by in vitro stimulation of lymphocytes in MLC with allogeneic or autologous lymphoblastoid cell line cells (*12*, *13*). If we make the assumption that the in vivo differentiation of NK cells from their precursors is similar to the in vitro generation of NK-like cytotoxicity, we can use this model to approach this problem. Our results, illustrated in text-figure 3, demonstrate an increase in MLC-generated anti-K562 cytotoxicity from PBL samples from periods of increasing NK activity in vivo. The NK-like cytotoxicity was generated from noncytotoxic cells; the PBL were first depleted of NK activity by passage over monolayers of EAγ. These results are quite similar to the increased cytotoxicity detected in CML assays when IFN is added to the MLC in vitro (*14*). However, we added no exogenous IFN in these cultures, and our results therefore reflect the increased ability to generate cytotoxic effectors, particularly against K562 targets, from PBL from patients treated with IFN. Although these results are certainly not a direct test of NK precursor activity, since we have no direct proof that the "NK-like" cytotoxicity is identical to standard NK cytotoxicity, these data are consistent with our hypothesis that IFN treatment augments the generation of NK cells from noncytotoxic precursors in vivo. As such, IFN may prove to be an extremely interesting agent for the study of the development and lineage of NK cells.

That continued IFN treatment failed to maintain NK activity at high levels was of considerable interest. Instead, NK activity declined following the peak attained in week 1 of treatment toward pretreatment NK levels. Our data strongly suggest that one major explanation for this phenomenon is the development of a refractory state to further IFN augmentation of NK cytotoxicity (text-figs. 4, 5). We found that PBL obtained before treatment, early during IFN treatment, or after completion of IFN treatment had NK activities that could be readily boosted in vitro by the pretreatment of cells with 100 U IFN for 60 minutes. However, PBL drawn from 1 week of treatment through 6 weeks of treatment showed little augmentation of NK cytotoxicity by in vitro pretreatment with IFN. These experiments were performed with pretreatment of PBL with IFN followed by washing of the pretreated PBL to eliminate IFN effects on target cells (*15*). Einhorn et al. (*16*) has also noted a diminished capacity of lymphocytes from IFN-treated patients to respond to IFN in vitro. Their results, in combination with ours, suggest that repeated doses of IFN will not have the ability to maintain high levels of NK cytotoxicity as cells become refractory to IFN stimulation. Our preliminary results (Golub S: Unpublished data) suggest that this refractory state extends to other forms of augmentation of NK cytotoxicity, because cells refractory to human leukocyte IFN (IFN-α) augmentation of NK cytotoxicity are also resistant to boosting by fibroblast IFN (IFN-β). The implications of these findings for proper dose and timing of IFN treatment are not clear; it is yet to be established that activation of NK cells is a crucial component of any antitumor effects of IFN. However, these results do suggest that alternative schedules, such as short treatment periods interrupted by rest periods, should be considered. This would be especially true if the refractory state associated with NK cytotoxicity can also be extended to other IFN-mediated biologic changes.

We also considered the possibility of the development of suppressor cells as an explanation of the declining NK activity seen after week 1 of IFN treatment. We attempted to find G10-adherent suppressor cells such as have been described in mouse cells exposed to carrageenan (*17*) or *Corynebacterium parvum* (*18*). Adherent cells have also been shown to inhibit spontaneous cytotoxicity against human tumor targets (*19*) and are required for the mitogen-induced suppression of human NK (*20*). Prostaglandins, a well-known secretion product of macrophages, can also suppress NK (*21*). Therefore, we considered the possibility that adherent cells, perhaps by means of prostaglandin secretion, were responsible for the decline in NK activity late in IFN treatment. As shown in text-figure 6, removal of G10-adherent cells failed to prevent the decline in NK activity or restore responsiveness to IFN. Similarly, removal of nylon-adherent cells did not restore activity of PBL drawn late in IFN treatment (table 1). Thus we could not demonstrate the participation of adherent suppressor cells. Furthermore, the addition of indomethacin had no appreciable effect on NK or response to IFN in vitro, making a prostaglandin-secreting suppressor cell unlikely to be involved in the declining NK activity in this system (text-fig. 7). We have yet to examine T-cell subpopulations that may show suppressive activity on NK function, and there is certainly the possibility of suppressor cells for the generation of NK activity from their noncytotoxic precursors. DeBoer et al. (*22*) have identified a human T-cell subpopulation that can suppress NK cell function, and Nair and Schwartz (*23*) have shown that concanavalin A-activated lymphocytes can suppress human NK activity. Non-T-lymphoid cells have been described to inhibit human K-cell function (*24*), and thus there is considerable precedent for the concept of lymphocyte regulation of human NK function. However, the addition of NK-depleted PBL from IFN-treated patients to fresh normal PBL failed to suppress NK activity of the normal PBL (Golub S: Unpublished observations), again indicating the lack of suppressors in this system for NK effector function. The possible contribution of suppressor cells for the development and expression of NK cytotoxicity is currently under study.

We would attribute the increase in NK activity demonstrated in patients treated with IFN to augmentation of NK cytotoxicity by mature NK cells and by the recruitment of noncytotoxic cells into the pool of available effector cells. The subsequent decline in NK cytotoxicity appears to be predominantly due to the inability of IFN to augment NK cytotoxicity from cells already pretreated in vivo with IFN. Other factors that may affect the regulation of NK cytotoxicity in vivo, such as redistribution of NK cells or effects on bone marrow precursor cells, must also be considered in discerning the systemic effects of this agent on the NK system.

Characterization of a Monoclonal Antibody Reactive With a Subset of Human Breast Tumors[1,2,3]

Dorothy Yuan,[4] Fred J. Hendler,[5,6] *and* Ellen S. Vitetta[4,7]

ABSTRACT—Fusion of spleen cells, from mice immunized against the human hormone-dependent breast cancer cell line ZR-75-1, with murine myeloma cells resulted in the establishment of a hybridoma cell line, HY59-H10 (H59). The purified monoclonal IgM produced by the hybridoma reacts with the most differentiated human breast tumor cell lines but not with cells derived from normal breast secretions or with numerous other malignant cell lines. Of 106 biopsy specimens examined, H59 bound to 54% of malignant breast specimens, to 83% of fibroadenomas, and to 82% of specimens containing fibrocystic disease. Binding could not be detected in uninvolved breast tissue.—JNCI 1982; 68:719–728.

Cells from human breast tumors may have distinct antigens that can elicit specific antibody and cell-mediated responses in patients with breast carcinoma (*1–3*). However, due to the complexity of the immune response, the specificities of the antisera have been difficult to assess (*4*). For a critical analysis of tumor-specific antigens, it would be advantageous to use a panel of monoclonal antibodies such as those that can be generated by somatic cell hybridization between myeloma cells and spleen cells obtained from immunized animals (*5*). This approach has been used to successfully generate monoclonal antibodies against human malignant cells (*6–9*). Our paper describes the characterization of the first of a series of monoclonal antibodies that we have generated against a malignant hormone-dependent human breast cell line, ZR-75-1 (*10*). This antibody is reactive with a distinct subset of well-differentiated human breast cancer cell lines, human breast carcinoma, and benign breast disease tissue but does not have activity against cells that bear HLA determinants, oncofetal antigens, CEA, or with the breast antigen detected by anti-murine GP52 sera (*11*). The antibody may, therefore, be recognizing a more differentiated breast cancer. Recently, a number of monoclonal antibodies against human breast tumor cells have also been described by other investigators (*12, 13*). None of those antibodies, however, have characteristics similar to those of the antibody described herein.

MATERIALS AND METHODS

Cell line used for immunization.—The ZR-75-1 cells, a line of human breast cancer cells, were selected as the source of antigen. The cell line was derived from metastatic breast cancer cells isolated from the ascitic fluid of a postmenopausal woman with metastatic infiltrating ductal carcinoma of the breast (*10*). The cells, which have been in continuous culture for 5 years, have epithelial morphology as determined by light and electron microscopy, have a human chromosomal karyotype, and are not a HeLa cell contaminant as determined by chromosomal banding and glucose 6-phosphate dehydrogenase isozyme analysis (*10*). These cells have retained estrogen, progesterone, androgen, glucocorticoid, and insulin receptors (*14, 15*). They do not produce the milk proteins casein and α-lactalbumin (*10*) but do make CEA (*16*).

Cultured cell lines.—Table 1 lists the cultured cell lines used in this study. ZR-75-1 cells were grown in Richter's improved minimum essential medium containing 10% calf serum, 10^{-8} M β-estradiol, 10^{-8} M insulin, 62 mg penicillin/liter, and 130 mg streptomycin/liter to maximize growth. The media for the other breast cell lines were similar in that calf serum and, where appropriate, hormones were substituted for FCS. Cells were removed from culture flasks by means of a rubber policeman. Cell aggregates were dissociated by passage through successively smaller-gauge needles. The resulting cell suspension contained more than 70% single cells. Alternatively, cells were removed by incubation for 5 minutes at 37°C in 1 mM EDTA.

ABBREVIATIONS USED: CEA=carcinoembryonic antigen; DMEM=Dulbecco's modified Eagle's minimum essential medium; FACS=fluorescence-activated cell sorter; FCS=fetal calf serum; GAM=goat anti-mouse immunoglobulin; H & E=hematoxylin and eosin; IP=immunoperoxidase; NCI=National Cancer Institute; PAGE=polyacrylamide gel electrophoresis; P=patient group; PBS=phosphate-buffered saline; RAκ=rabbit anti-mouse κ; RAλ=rabbit anti-mouse λ; RAμ=rabbit anti-mouse μ; FITC-RAμ=fluorescinated RAμ; RIA=radioimmunoassay; SDS=sodium dodecyl sulfate; UTHSCD=The University of Texas Health Science Center at Dallas.

[7] We thank the following for providing us with cells: the NCI Breast Cancer Task Force Cell Culture Bank (Dr. C. B. Piczak, NCI, and Dr. E. Jensen, Mason Research Institute, Rockville, Md.); Dr. M. E. Lippman and Dr. W. R. Kidwell, NCI; Dr. R. G. Smith, Department of Medicine, and Dr. P. MacDonald and Dr. J. C. Porter, Department of Obstetrics, Gynecology, and Physiology, UTHSCD. We also thank Ms. E. Carlton, Ms. L. Trahan, Dr. D. Richardson, Ms. J. Tseng, and Mr. D. R. Quick, UTHSCD, for expert technical assistance; and Ms. G. A. Cheek and Ms. D. Marcoulides, UTHSCD, for secretarial assistance. We are also grateful to Dr. E. P. Frenkel, Department of Internal Medicine, and Dr. Fred Silva, Department of Pathology, UTHSCD, and Dr. William Kingsley, Department of Pathology, Baylor Medical Center, Dallas, Tex., for their review of the scientific data. We are especially indebted to Dr. Jonathan W. Uhr, Department of Microbiology, UTHSCD, for his constant support and advice and his assistance with the manuscript.

TABLE 1.—*Cells used for panel testing*

Designation	Cell Type	Original investigator (reference)
Cultured breast cell lines		
ZR-75-1[a]	Breast cancer, infiltrating ductal	Engel LW, et al. (*12*)
MCF-7[a]	Breast cancer, infiltrating ductal	Soule HD, et al. (*29*)
MCF-7*[b]	Breast cancer, infiltrating ductal	Soule HD, et al. (*29*)
MDA-MB-231[b]	Breast cancer	Cailleau R, et al. (*30*)
BT20[b]	Breast cancer, infiltrating ductal	Lasfargues EY, et al. (*31*)
T47D[b]	Breast cancer, infiltrating ductal	Kaydar I, et al. (*32*)
HBL 100[b]	Normal breast	Gattney EV (*33*)
WRK-1[c]	DMBA rat mammary tumor	Kidwell WR, et al. (*34*)
Cultured carcinoma cell lines[d]		
#50	Squamous carcinoma; cervix	Porter JC, et al. (*35*)
#6	Squamous carcinoma; colon	Porter JC (unpublished data)
#117	Adenocarcinoma; ovary	Porter JC (unpublished data)
#296	Adenocarcinoma; endometrium	Kurameto H, et al. (*36*)
#194	Choriocarcinoma; trophoblast	Patillo RA, Gey GO (*37*)
#253	Adenocarcinoma, endometrium	Porter JC, Gal D (manuscript in preparation)
#265	Adenocarcinoma; endometrium	Porter JC (unpublished data)
#168	Squamous carcinoma; cervix	Porter JC (unpublished data)
#230	Squamous carcinoma; cervix	Porter JC (unpublished data)
#110	Undifferentiated carcinoma; ovary	Porter JC (unpublished data)
Lymphocytic cell lines		
NALL-1[e]	Non-B-, Non-T-cell lymphocytic leukemia	Miyoshi I, et al. (*28*)
NALM-1[e]	Pre-B-cell leukemia	Minowada J, et al. (*38*)
SMS-JiGi[e]	B-lymphoblastoid (Epstein-Barr virus transformed)	Smith RG (unpublished data)
BCL$_1$	Murine B-cell leukemia	Slavin S, Strober S (*39*)
Neuronal cell lines[e]		
U251-MG	Glioma	Ponten J (*40*)
SMS-KAN	Neuroblastoma	Biedler JL (*41*)
SH-SY-5Y	Neuroblastoma	Ross RA, et al. (*42*)
Melanocyte–melanoma cell lines[e]		
U1 I	Normal melanocytes	Meyskens FL, et al. (*43*)
M1RW	Melanoma	Meyskens FL, Fuller BB (*44*)
Noncultured cells		
Human amnion	Normal	Porter JC (unpublished data)
Peripheral blood lymphocytes	Normal	Donor: Yuan D Donor: Vitetta ES

[e] Obtained from Dr. R. G. Smith, UTHSCD.

Animals.—Female BALB/c mice (6–8 wk old) obtained from Cumberland Farms, Clinton, Tenn., were immunized ip with 10^6 ZR-75-1 cells three times at 2-week intervals and challenged iv with the same cell dose 3 days before being killed.

Cell fusion.—Spleen cells from immunized animals were fused with P_3×63 Ag 8 myeloma cells (*17*), according to the methods described by Kennett (*18*). Splenocytes and myeloma cells were mixed and incubated at a ratio of 5:1 in the presence of 33% polyethylene glycol 1000 (J. T. Baker Chemical Co., Phillipsburg, N.J.) in serum-free DMEM (GIBCO, Grand Island, N.Y.). Cells were diluted in DMEM containing hypoxanthine, aminopterin, and thymidine (Sigma Chemical Co., St. Louis, Mo.) (*19*) and seeded in 96-well plates (Linbro Scientific Inc., Hamden, Conn.) at 5×10^4 myeloma cells/well. Visible colonies appeared 10–14 days after hybridization.

RIA.—Hybridoma secretions were screened by an indirect RIA modified from the methods described by Segal and Klinman (*20*). Target cells (10^5/well), briefly fixed with 0.125% glutaraldehyde, were incubated with secretions for at least 3 hours. After washing with PBS (pH 7.3) containing 5% horse serum, approximately 50,000 cpm (1×10^7 cpm/μg) ^{125}I-labeled affinity-purified GAM were added. After 3 hours of incubation, cells were washed with 0.5% Nonidet P40 in 0.15 *M* NaCl–0.01 *M* Tris (pH 8) and air dried. The wells were cut with a hot wire device and counted in a gamma counter (model #1195; Nuclear Chicago Tractor Analytic; Amersham/Searle Corp., Arlington Heights, Ill.). Direct binding with ^{125}I-labeled IgM purified from hybridoma ascites fluid was performed in a similar manner.

Radiolabeling of hybridoma secretions.—Hybridoma cells (10^7) were cultured for 6–8 hours at 10^6 cells/ml in leucine-free Eagle's minimum essential medium (GIBCO) supplemented with 10% FCS, glutamine, antibiotics, and 1 mCi [^{3}H]-leucine (134 Ci/mmol; Amersham/Searle Corp.). Cells were removed by centrifugation, and aliquots of the dialyzed supernatants were treated with various antibodies and *Staphlococcus aureus* (*21*). Immune complexes were eluted in 1% SDS containing 8 *M* urea, and the eluates were analyzed by PAGE [7.5% polyacrylamide gels containing SDS (SDS-PAGE)] (*21*). Gels were fractionated with a gel slicer (Hoefer Scientific Instruments, San Francisco, Calif.). The slices were treated with 0.2% SDS for 24 hours, scintillation cocktail was added (Redi-Solv.; Beckman Instruments, Inc., Fullerton, Calif.), and the samples were counted in a scintillation counter (model #LS 330; Beckman Instruments, Inc.).

Radioiodination of antibodies.—Affinity-purified GAM or purified hybridoma IgM were labeled with Na^{125}I by lactoperoxidase catalyzed iodination (*22*). Fifty μg protein in 100 μl PBS was incubated with 1 mCi Na^{125}I (Amersham/Searle Corp.), 5 μg lactoperoxidase (Sigma Chemical Co.), and 5 μl 0.03% H_2O_2 for 2 minutes at 24°C. The reaction was terminated by the addition of 1 ml PBS, and the sample was exhaustively dialyzed against PBS. An equal volume of FCS was added after 1 hour of dialysis to retard degradation of the iodinated protein.

Antisera.—Each of the affinity-purified antibodies has been characterized as described below or in the indicated reference:

1) RAM (*23*).

2) RAμ (*23*).

3) GAM: This antiserum (*24*) was affinity purified on Sepharose-mouse IgG. It had reactivity against γ-, κ-, and λ-chains.

4) RAκ: TEPC-15 and other murine myeloma proteins were obtained from Litton Bionetics, Kensington, Md. A New Zealand White rabbit was immunized with 100 μg TEPC-15 (α,κ) in complete Freund's adjuvant. Four weeks later and at 2- to 20-week intervals thereafter, the rabbit was given booster injections of 25 μg TEPC-15 in incomplete adjuvant. The resulting serum contained antibodies to murine α-, κ-, and λ-immunoglobulin chains, as assessed by indirect precipitation of a panel of ^{125}I-labeled myeloma proteins. The serum was affinity purified on Sepharose bound to MOPC-21 (γ,κ) and absorbed sequentially with Sepharose bound to MOPC-104E (μ,λ) and MOPC-315 (α,λ). The resulting affinity-purified antibody was concentrated to 1.0 mg/ml by negative-pressure dialysis and was stored at −70°C. As determined by RIA, the antibody was specific for κ [positive reaction with RPC-5 (γ,κ), MOPC-21 (γ,κ), TEPC-183 (μ,κ), and TEPC-15 (α,κ)] and negative for λ, α, and μ [as determined by RIA with the use of MOPC-315 (α,λ), and MOPC-104E (μ,λ)].

5) RAλ: In a procedure similar to that described in category 4 above, a rabbit anti-RPC-20 (free λ-chain) was affinity purified on Sepharose-MOPC-104E (μ,λ) and absorbed with Sepharose bound to TEPC-15 (α,κ), TEPC-183 (μ,κ), and MOPC-21 (γ,κ). The anti-λ-antibodies were shown to be specific by indirect precipitation in which the same panel of myeloma proteins, described in category 4 above, was used.

Immunofluorescence staining.—Cell suspensions either were stained directly or were fixed first with 4% paraformaldehyde for 15 minutes. Balanced salt solution containing 0.2% sodium azide was used for all washes, and cells were maintained at 4°C. Aliquots of cells were incubated with various concentrations of primary antibodies at 5×10^6 cells/ml for 20 minutes. After washing, the cells were stained with the secondary antibody FITC-RAμ (*25*) for 10 minutes. Analysis on the FACS was performed as described in (*26*).

Patient tissue specimens.—Tumor tissues obtained from patients undergoing breast biopsy or mastectomy were frozen in liquid nitrogen. Cryosections (6–8 μm) were prepared from the frozen samples in a cryostat. Representative sections of each tumor were stained with H & E, and the presence of tumor cells was confirmed. Cryosections were fixed in 50% acetone-PBS, washed with PBS, and dried. The area of the slide containing the section was covered with 100 μl ^{125}I-labeled H59 IgM or an irrelevant hybridoma antibody, ^{125}I-labeled BCL$_1$ IgM (*27*). Sections were incubated for 3 hours at 24°C and washed with PBS-FCS (5%). The sections were exposed to X-ray film (Kodak X-Omatic) for 16 hours before development of the film.

RESULTS

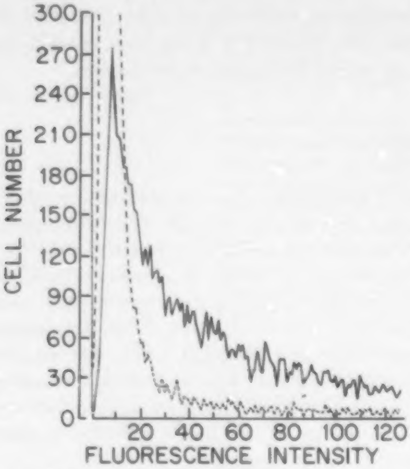
Selection of hybridomas.—In a hybridization of splenocytes from a mouse immunized with ZR-75-1 cells, approximately 80% of the seeded wells contained clones that survived the selection medium. Of these, 20 clones secreted antibodies that bound to the human breast tumor cells used for immunization. Only one hybridoma, H59, did not bind to the discriminator cell line NALL-1 (*28*) used to detect antibodies against "common" human cell surface antigens. This hybridoma was further cloned by limiting dilution and has been maintained for more than 8 months in tissue culture without loss of secretory ability.

Analysis of secreted antibodies.—H59 cells were labeled with [^{3}H]leucine, and an aliquot of the dialyzed secretion was analyzed by SDS-PAGE (without immunoprecipitation). The remainder of the secretion was immunoprecipitated with antisera directed against mouse immunoglobulin, κ-chain, λ-chain, and μ-chain (RAM, RAκ, RAλ, and RAμ). Analysis of the immunoprecipitates by SDS-PAGE (not shown) indicated that the clone was secreting IgM$_\kappa$, as well as the immunoglobulin of the parent myeloma line (IgG$_{1\kappa}$). The IgM$_\kappa$ does not bind to protein A.

Purification and characterization of the monoclonal antibody from H59 cells.—The cells from clone H59 were injected into mineral oil-primed (0.2 ml/mouse) BALB/c mice. The globulin from the ascitic fluid generated in this manner was prepared by (50%) ammonium sulfate precipitation, and the dissolved precipitate was fractionated on an AcA 34 Biogel (LKB Instruments, Rockville, Md.) column equilibrated in Tris-buffered saline (pH 7) to separate IgM and IgG. The fractions containing IgM were pooled and concentrated by lyophilization. The purified IgM was radiolabeled by iodination and immunoprecipitated by the same panel of antibodies used for the [^{3}H]leucine-labeled secretion. SDS-PAGE analysis of the labeled IgM and immunoprecipitation analysis confirmed the purity of the preparation and that the H59 was an IgM$_\kappa$ antibody.

Binding of ZR-75-1 cells.—To demonstrate the ability of the purified IgM to specifically bind to ZR-75-1 cells, the purified IgM was used to stain fixed ZR-75-1 cells by indirect immunofluorescence. Fluorescinated affinity-purified RAμ was used as a secondary reagent, and the cells were analyzed on the FACS. As indicated by the plot of scatter and fluorescence intensity for each cell, (fig. 1A), the cells were highly heterogeneous in size. Some of the heterogeneity may be attributed to multinucleated cells and small cell clumps. Nevertheless, from a plot of cell number versus fluorescence intensity derived from figure 1A, we calculate that more than 78% of the population were bound by antibody under saturating conditions. The nonspecific binding (fig. 1B), as determined by the percentage of cells stained in the absence of primary antibody or in the presence of the nonspecific antibody BCL$_1$ IgM, was less than 10%.

When viable (instead of fixed) ZR-75-1 cells were used for staining, higher concentrations of antibody were need for saturation, and a lower percentage (net, 53%) of the ce were stained (text-fig. 1). All dead cells in the preparatio as determined by scatter characteristics, were excluded the analysis.



Text-figure 1.—FACS profile of fixed ZR-75-1 cells stained with ^{125}I-labeled H59. Approximately 1×10^6 paraformaldehyde-fixed ZR-75 cells were incubated with A) 2 μg H59 or B) no antibody for 20 min at 4°C. After washing, cells were stained with 5 μg FITC-RAμ for 10 min and again washed. The light scatter and fluorescence intensity of each cell is represented by a dot.

Testing of H59 binding to normal and malignant cells.—Tl above results had established that the antibody produc by clone H59 binds to ZR-75-1 cells but not to anoth human cell line, NALL-1. The next step was to test mo extensively the activity of H59.

Either ^{125}I-labeled IgM from clone H59 or an irreleva monoclonal ^{125}I-labeled IgM was incubated with a numb of cell lines fixed in the same manner as were the ZR-75 cells (text-fig. 2; table 1). Of the 6 human breast cancer c lines tested (MCF-7* are MCF-7 cells obtained from second source), only 3 reacted with the IgM secreted H59. Most importantly, the monoclonal IgM does not bi to a breast cell line derived from normal human brea secretions, HBL-100, or to a 7,12-dimethylbenz[*a*]anthr cene-induced rat mammary cancer cell line, WRK-1.

In addition, the antibody was tested against a panel carcinomas. With the exception of the carcinomas deriv from endometrial cells, which were moderately positive, others bound background levels of radioactivity.

Binding to cell lines of lymphoid, melanocytic, and ne ronal origin, as well as to a few cell types not maintaine in culture, was evaluated. All of these lines with the exce tion of a glioma cell line demonstrated negligible binding

Reactivity of H59 IgM with fresh tumor tissue.—A method w devised for autoradiographic labeling of patient tumors (

Text-figure 2.—Binding of H59 IgM to breast cell lines and other cell types. Fixed cells (1×10^5) from each cell line were incubated with 50,000 cpm of either ^{125}I-labeled H59 IgM (●) or with a control, ^{125}I-labeled BCL$_1$ IgM (△). The amount of radioactivity bound by each cell type after extensive washing was determined by direct counting in the gamma counter. *See* table 1 for listing of cells used.

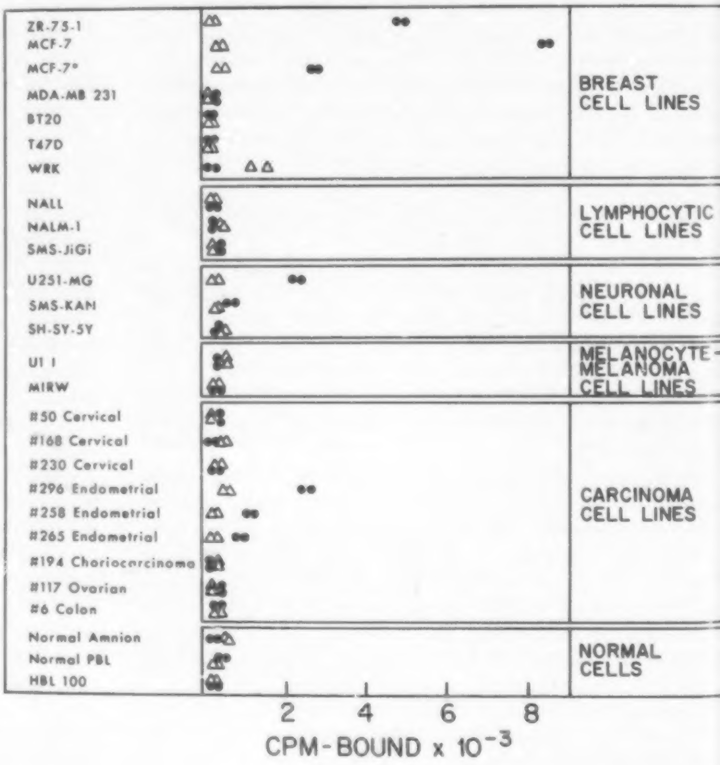


TABLE 2.—*Labeling of tissue sections by H59 IgM*

Pathologic diagnosis	Tumors tested, total No.	H59-binding tumors	Percent positive
Breast carcinoma	71	38	54
Fibroadenoma	11	9	84
Fibrocystic disease	24	20	83
Total	106	67	63

"Materials and Methods"). To ascertain the validity of the method, we stained cryosections of ZR-75-1 and T47D cell pellets. As seen in figure 2 (*left panel*) the reactive cell line ZR-75-1 was uniformly labeled with ^{125}I-labeled H59 IgM (100%), and the nonreactive cell line T47D showed only background staining; the control antibody ^{125}I-labeled BCL$_1$ IgM (*right panel*) did not bind to any of the sections. To determine the sensitivity of this method, we prepared cryosections of cell pellets from mixtures of T47D cells containing decreasing percentages of ZR-75 cells (fig. 2). It is apparent that autoradiography can specifically detect 1% positive cells in a mixed population. The sensitivity of this method has been compared with that of IP staining in which adjacent cryosections of the same cell pellet were used. The sensitivities appear to be within the same order of magnitude. Autoradiography offered the advantage of allowing the simultaneous processing of a large number of specimens without laborious examination of individual slides.

The cryosections obtained from a total of 106 breast biopsy specimens were evaluated by means of autoradiography. Figure 3 shows the autoradiographic staining of representative cryosections. Cryosections from some specimens diagnosed as infiltrating intraductal breast carcinoma stained as extensively as did ZR-75-1 cells (P-6), whereas other sections stained with less uniformity but contained regions of intense antibody binding (P-2, P-5). There are also sections of tumors from many patients with intraductal carcinoma that did not stain significantly above the background (P-3). A cryosection from noninvolved breast tissue obtained from a patient with a highly reactive tumor (not shown) did not react with the antibody. Included in figure 3 are also the cryosections of patients with fibrocystic disease (P-1) and fibroadenoma (P-7). These sections also stained with the H59 antibody. However, the pattern of labeling is different from that seen in carcinoma sections.

Figure 4 compares the pattern of autoradiographic labeling with cells that can be detected in the sections by H & E staining. The areas of H59 binding can be directly correlated with regions of tumor cells, and regions to which the antibody does not bind are associated with an absence of tumor cells. The correlates of binding to fibroadenomas and fibrocystic diseased tissue are also associated with regions of increased cellular density. Table 2 shows the cumulative results of all breast tissue sections we have analyzed. H59 antibody binds to 54% of tissue sections from patients with pathologically documented breast cancer. It binds to 84% of fibroadenomas and 82% of fibrocystic diseased tissue.

DISCUSSION

We have established the hybridoma cell line H59, resulting from the fusion of spleen cells, from a mouse immunized against a human breast cancer cell line, with a murine myeloma cell. The purified monoclonal IgM antibody produced by this hybridoma reacts with a restricted subset of human breast cancer cells.

H59 is reactive with the cell lines ZR-75-1 and MCF-7 which are derived from human infiltrating intraductal breast cancer tissue. These cell lines have maintained a well-differentiated glandular morphology and contain estrogen as well as other hormone receptors (*14*). H59 binds less well to a second clone of MCF-7 cells, MCF-7*, which are known to have fewer estrogen receptors (*45*). The antibody does not react with T47D, a cell line with trace amounts of estrogen receptor and high progesterone receptor (*45*) or with cell lines having no estrogen receptor. It does not bind nonhuman mammary cancer cells known to have mouse mammary tumor virus (*46*). It does not bind cell line HBL-100 which may be derived from normal human mammary secretions. Thus H59 binds to the most differentiated of human breast cancer tissue culture cells.

H59 was tested against a variety of normal and neoplastic cell lines to establish its specificity for breast cell carcinomas. The results of the tests indicate that the reactivity of the H59 IgM is highly restricted for the following reasons: 1) The antibody does not seem to detect the oncofetal antigen shared by normal fetal brain tissue and some breast tumor cells (*47*), inasmuch as both the MBA-MB 231 and BT 20 cell lines have been shown to express oncofetal antigens (*4, 48*), and the H59 IgM does not react with these lines. 2) The antigen recognized by H59 is probably not the CEA (*49*) present on many colon carcinomas and some normal tissues, since H59 does not bind to BT 20 cells, which have been shown to express this antigen (*48*). H59 also does not bind to a number of adenocarcinoma cells, including colon carcinoma cells which most probably express the CEA. Furthermore, H59 does not bind to ^{125}I-labeled CEA (Roche Laboratories, Nutley, N.J.) (Yuan D, Vitetta ES; Unpublished observations). 3) H59 IgM does not recognize an antigen that shares determinants with the GP52 viral antigen (*50*) because T47D cells, which express the viral antigen (*46*), are negative with H59. Moreover, GP52 found in breast tumor cells is an intracellular antigen (*11*), whereas H59 antigen apparently is expressed on the cell surface. Preliminary biochemical characterization of the H59 antigen indicates that it constitutes two monomers of approximately 30,000 daltons with isoelectric points ranging between pH 5.5 and 6 (*51*). H59 antibody has some reactivity with adenocarcinoma cells derived from endometrial tissues and with the glioma cell line. The reactivity may be due either to cross-reactivity or to a limited expression of the antigen. Therefore, we conclude that the reactivity of H59 antibody is highly, although not exclusively, restricted to human breast tumor cells.

To test the ability of H59 antibody to bind tissue sections from breast cancers, we developed a rapid, reproducible radioautographic assay. Mesa-Tajada et al. (*11*) and Schlom et al. (*12*) have used IP staining as a means of determining breast specimen reactivity. Although our method necessitates the use of radiolabeled antibodies that have a defined half-life, it has several advantages: 1) It is simpler inasmuch as it is a direct rather than an indirect immunoassay; 2) it is less prone to artifacts associated with the secondary antibody, the IP technique, or the diaminobenzidine color reactions; and 3) evaluation of samples is more rapid. The assay has been quantified, and it appears to be as sensitive as the IP assay.

With the radioautographic assay we have determined that H59 reacts with a majority of human breast cancer tissue specimens. It also binds to an even greater proportion of fibrocystic diseased tissues and fibroadenomas. Binding studies with other monoclonal antibodies (Hendler FJ, Yuan D, Vitetta ES; manuscript in preparation) show that the tissue specimens that do not bind to H59 do bind to other monoclonal antibodies with broader reactivity for breast carcinomas.

We postulate that H59 may be reacting with a differentiation antigen restricted to a subset of more differentiated breast cancers. The evidence in support of this hypothesis is that H59 binds only to the most differentiated human breast cancer cell lines, to the majority of abnormal tissue from patients with fibrocystic disease and fibroadenomas (which are both benign hyperplasias of breast tissue), and to only a portion of human breast cancer tissues. This putative surface antigen may be coexpressed with the intracellular estrogen receptor because our panel test suggests that H59 reacts only with estrogen receptor-positive cell lines. Studies are in progress to analyze the possible relationship of H59 binding and the presence of estrogen receptor in patient samples. If one assumes that breast cancers that have retained differentiation antigens have a better prognosis, as is the case with estrogen receptor-positive cancers (*52*), the presence of H59 antigen in a tumor might have important clinical implications.

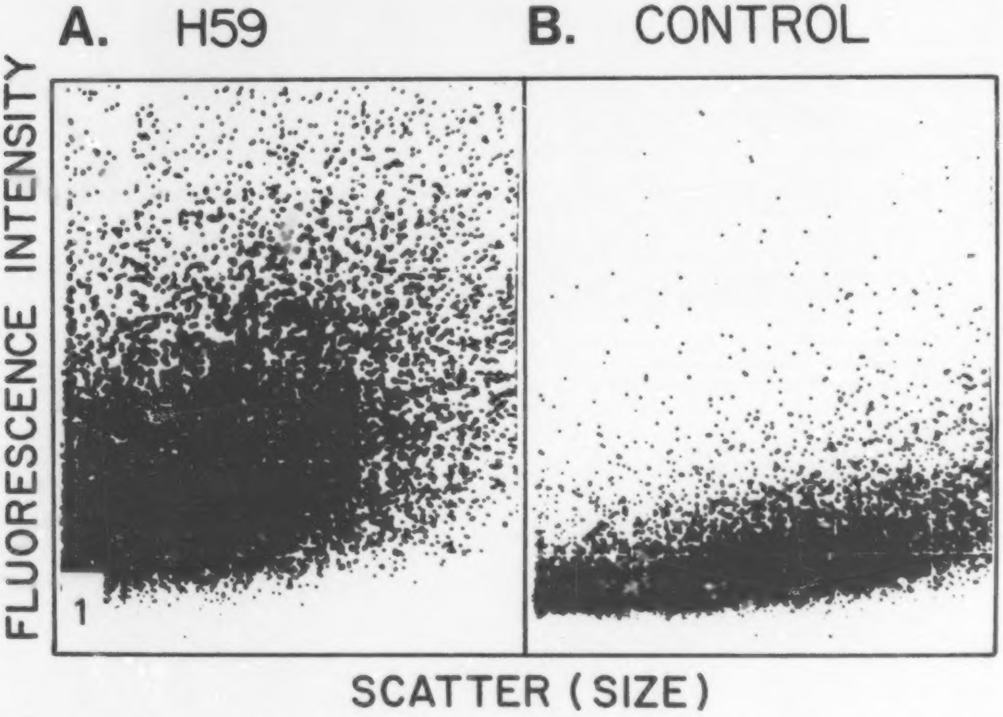

Figure 1.—FACS analysis of freshly prepared ZR-75-1 cells. Cultured ZR-75-1 cells were removed from culture flasks with 0.01 *M* EDTA. After washing, ≈5×10^5 cells were stained with either 10 μg H59 (——) or an irrelevant hybridoma antibody, BCL$_1$ IgM (- - -), for 20 min at 4°C. Cells were then washed and stained with 10 μg FITC-RAμ for 10 min at 4°C. The plot of cell number vs. fluorescence intensity was derived by FACS analysis. The percentage of positively stained cells was calculated by determining the number of cells in channels 10-127.

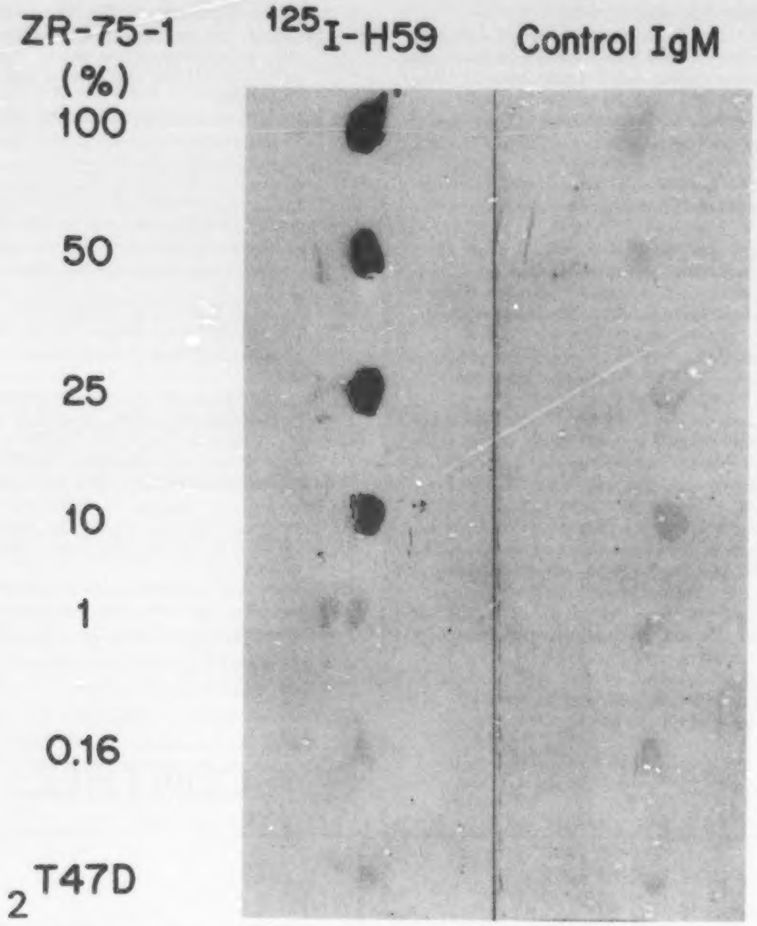

FIGURE 2.—Binding of ^{125}I-labeled H59 to cryosections of cultured cell lines. Cultured ZR-75-1 and T47D cells were harvested and resuspended as single cell suspensions. Varying proportions of cells from each cell line were mixed, centrifuged, and the pellets frozen and sectioned. The cryosections were fixed in acetone-PBS and incubated with either ^{125}I-labeled H59 or ^{125}I-labeled control IgM (BCL$_1$ IgM) (100,000 cpm/section) for 3 hr at 24°C. After four washes with PBS containing 5% serum, the sections were dried and exposed to X-ray film for 16 hr before development of the film.

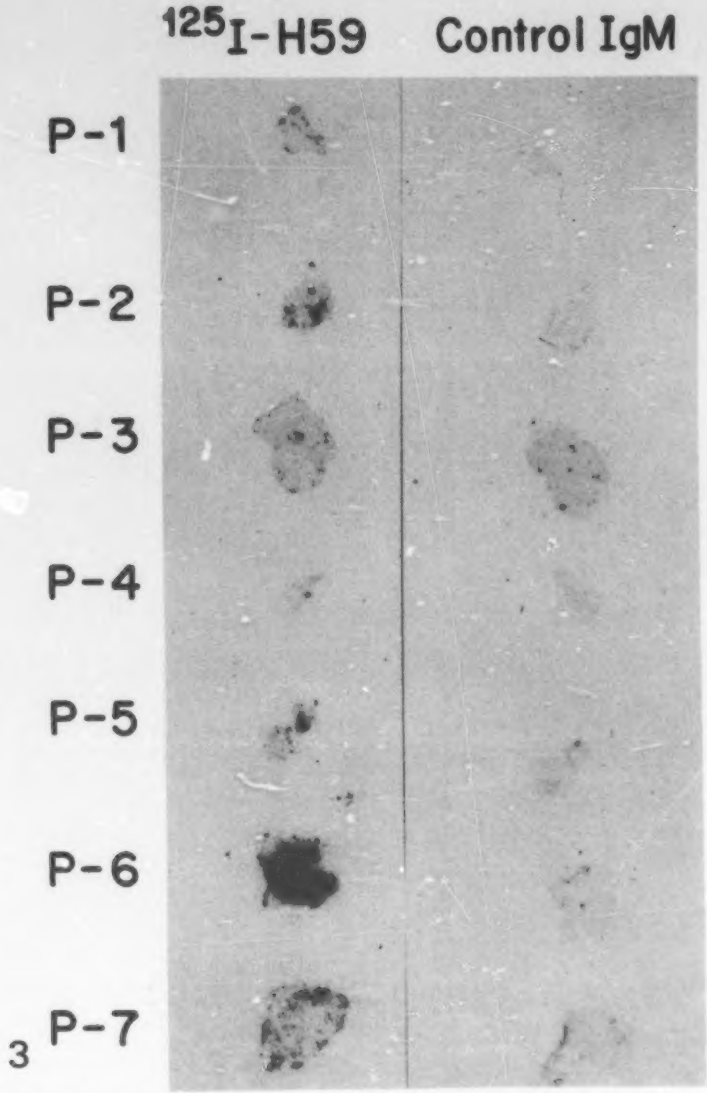

FIGURE 3.—Binding of ^{125}I-labeled H59 to cryosections of excised tumors. Tumors were frozen, sectioned, and stained as in fig. 2. Histologic diagnosis was as follows: P-1, fibrocystic disease; P-2, intraductal carcinoma; P-3, intraductal carcinoma; P-4, fat necrosis; P-5, intraductal carcinoma; P-6, intraductal carcinoma and fibrocystic disease; and P-7, fibroadenoma.

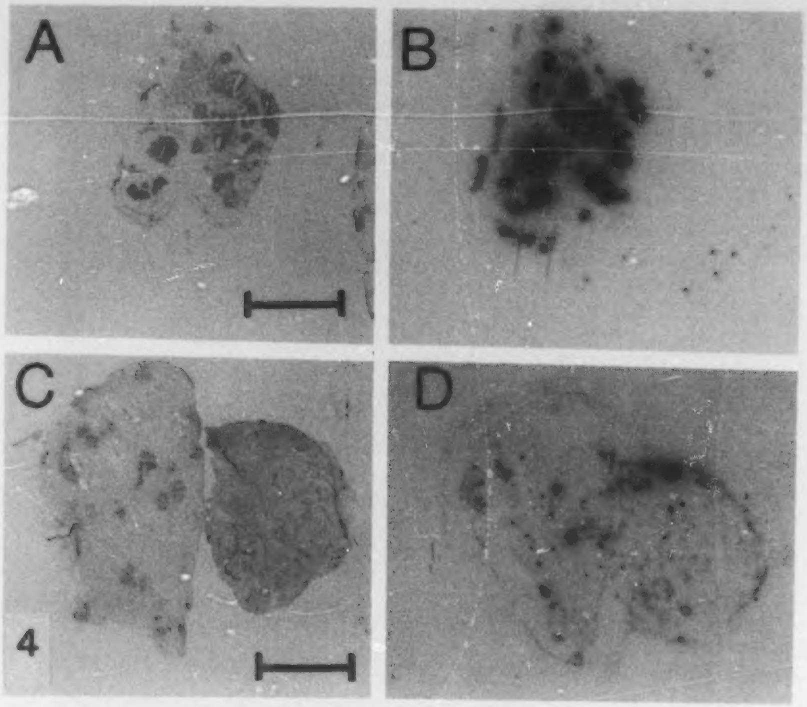

FIGURE 4.—Comparison of cryosections for ^{125}I-labeled H59 binding and histopathology. Cryosections from patients with intraductal carcinoma (4A, 4B) or fibrocystic disease and fibroadenoma (4C, 4D) were either stained with ^{125}I-labeled H59 (4B, 4D) or stained with H & E (4A, 4C). Areas of intense staining by both methods represent malignant cells. *Bar* = 5 mm.

Epidemiologic and Age-Dependent Data on Multiple Myeloma in Austria[1,2]

Heinz Ludwig,[3,4,5] **Elke Fritz,**[3,4] *and* **Hans P. Friedl**[6]

ABSTRACT—The mortality rates for multiple myeloma showed an increasing trend between 1969 and 1979, when multiple myeloma accounted for 6‰ of the reported cancer deaths in Austria. The median age at diagnosis was relatively high: 68.5 years for males and 69.0 years for females. The age-corrected male:female ratio of 1.23:1 indicated a higher incidence of multiple myeloma in males. Age-standardized (standard population for Europe) incidence rates amounted to 1.5/100,000 male inhabitants and 1.2/100,000 female inhabitants/year. In a subsample of patients with multiple myeloma, the paraprotein types as well as the κ:λ ratio resembled the frequency distribution of normal immunoglobulins. There were no age-related differences for the stages of the disease and the poor risk factors at diagnosis for patients 65 years old or younger or for those over 65 years of age at diagnosis. Survival rates were significantly higher for younger patients than for older ones, with a 50% survival time of 45 and 26 months, respectively. The differences resulted solely from the dissimilar general life expectancies in both groups, and survival rates with strict regard to multiple myeloma proved to be identical in younger and older patients.—JNCI 1982; 68:729–733.

Studies on the epidemiology of multiple myeloma already were done in the early 1940's, but data have become more reliable only after the accuracy and ease of diagnosis had been improved by the introduction of paper and later of immune electrophoresis (*1*). Data dealing with the sexual and ethnic distribution of myeloma patients as well as the overall incidence of myeloma are now available for several countries. So far no epidemiologic survey has been published for Austria, a country with an age distribution typical for central Europe, namely, a large percentage of elderly inhabitants. With this report we aim to close this information gap on the incidence of and mortality from multiple myeloma in Austria and investigate the influence of age at the time of diagnosis on the clinical course of the disease.

MATERIALS AND METHODS

Population.—At the end of 1979 Austria had 7.4 million inhabitants (47.2% males and 52.8% females) who were almost exclusively Caucasians. The average life expectancy at birth was 66.6 years for males and 73.7 years for females. Of the total population, 29.6% were younger than 20 years. As in other European countries, a relatively large portion, 18.5% of the total population, were over 60 years old.

Cancer registry.—Since 1970 the cancer registry of the Austrian Central Statistical Bureau requires notification of all new cases of cancer by all hospitals, all departments of radiology, and all institutes of pathology, thus covering the total population. The data used in this paper include incidence rates and death rates for multiple myeloma (code 203) from 1969 through 1979 as well as other cancers categorized under "neoplasms of lymphatic and hemopoietic tissues" (codes 202, 204, 205, 206, and 207) according to the International Statistical Classification of Diseases, Injuries, and Causes of Death (*2*) and general population statistics.

Hospital patients.—Between 1970 and 1980, 134 patients with multiple myeloma were treated as inpatients at the Department of Medicine II, University of Vienna. In 128 cases sufficient data were available to analyze the age distribution at the onset of the disease, and in 114 cases it was possible to study the distribution of paraprotein types and the survival times. Myeloma cases were staged in 70 patients at the time of diagnosis according to the staging system of Durie and Salmon (*3*). Seventeen of these patients received an identical first course of polychemotherapy consisting of melphalan (0.5 mg/kg body wt), cyclophosphamide (15 mg/kg body wt), vincristine (1.4 mg/m^2), and prednisone (40 mg on days 1–7 and 20 mg on days 8–14). Selected clinical parameters and laboratory findings were compared for early versus late age of manifestation.

Statistical evaluation.—The crude statistical data were converted into age-specific incidence and mortality rates. For comparisons those values were age standardized with the use of the standard population for Europe published in 1976 (*4*). For the examination of the significance of trends, the sign-trend test by Cox and Stuart (*5*) was applied. Survival rates were calculated from the observed survival times according to the life table method (*6*). For comparisons of survival by the log rank test (*7*), four additional life table graphs were established: P for the entire population of patients with multiple myeloma, G for the entire reference population, GY for the reference population 65 years of age or younger, and GO for the reference population over 65 years of age.

The general life expectancies G, GY, and GO refer strictly to the observed groups; i.e., for each patient sex and age at diagnosis were entered into the probability rates, and the weighed probabilities were calculated for 7 consecutive years. For each group and each relevant point in time t, the number of expected deaths E was calculated by age and sex standardization of the general mortality by means of the following formulas: $E_Y(t) = (p_P(t) - p_G(t) + p_{GY}(t)) \times N_Y(t)$ and $E_O(t) = (p_P(t) - p_G)t) + p_{GO}(t)) \times N_O(t)$, where p stands for probability of death and N_Y and N_O denote the

number at risk in the specific group of patients. Significances according to the log rank test and for the evaluation of clinical parameters were evaluated by the chi-square test.

RESULTS

For 1969 and 1979 the exact number of reported deaths from multiple myeloma, Hodgkin's disease, and other lymphoreticular cancers are given in table 1. During that decade the mortality rate for multiple myeloma and other lymphoreticular neoplasms increased slowly, whereas the death rates for Hodgkin's disease decreased. Text-figure 1 shows the statistically significant time trends expressed as mortality per 100,000 members of a European standard population. Neither the percentage of multiple myeloma from all deaths caused by lymphoreticular cancers (range: 13.6–17.2%) nor the proportion of cancer deaths due to multiple myeloma (range: 4.4–6.2‰) varied systematically over the observed period of time.

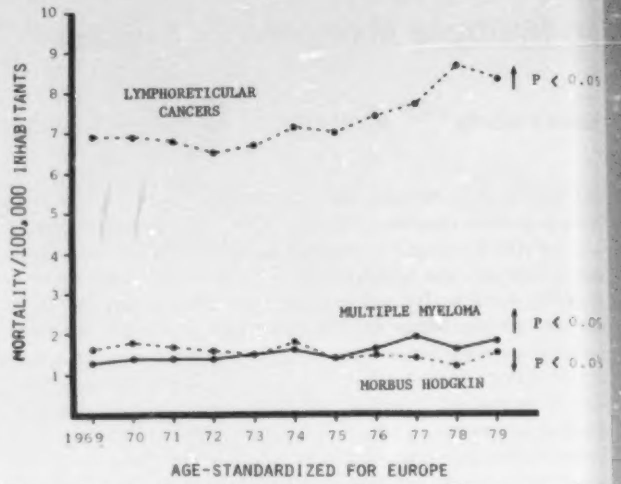
The incidence of multiple myeloma in Austria was of the same magnitude as the mortality and in 1979 accounted for 139 (13.5%) of the 1,026 cases registered as lymphoreticular cancers. For multiple myeloma the age distribution at diagnosis was slightly skewed to the right with a median of 68.9 years of age (68.5 yr for males and 69.0 yr for females). The 6th and 7th decades of life contained the peak incidence, considerably fewer patients were over 80 years of age at diagnosis, and multiple myeloma rarely occurred below the age of 40. The age pattern remained constant with an almost identical median for each year between 1970 and 1979.

The age-specific incidence rates per 100,000 inhabitants for 1979 are presented in text-figure 2. Age-standardized incidence rates from 1970 to 1979 for males and females separately are shown in text-figure 3. After 1975 the sex ratio remained rather constant (males:females=1.23± 0.08:1), and the curves seemed to have stabilized into a steadily increasing frequency of newly registered myeloma cases as opposed to the probable random variations during the first 5 years of compulsory notification of cancers to the cancer registry. When the average age-standardized incidence for 1975–79 (1.5/100,000 persons and year for males and 1.2/100,000 persons and year for females) was compared to the incidence rates for 16 other European countries reported in 1979 (*4*), Austria was located in the 13th and 12th place for males and females, respectively, following Yugoslavia and the German Democratic Republic and preceding Poland (text-fig. 4).

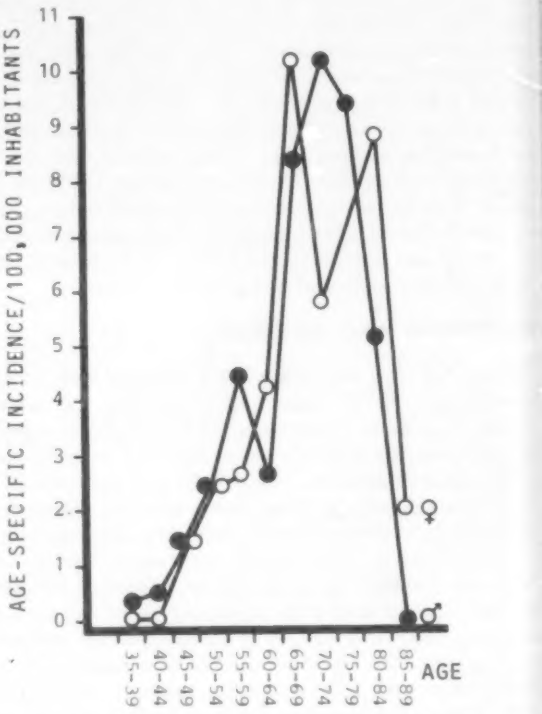
Analysis of the 134 patients diagnosed and treated at the Department of Medicine II, University of Vienna, between 1970 and 1979 yielded an age distribution very similar to that of the myeloma patients registered for all of Austria. The median age at manifestation was also very close to the respective parameter of the total population, namely, 68.2 years. Apart from small random variations, the ratio of patients 65 or younger to those 65 or older was constant throughout the observed decade.

TABLE 1.—*Deaths from multiple myeloma, Hodgkin's disease, and other lymphoreticular cancers in Austria: 1969 and 1979*

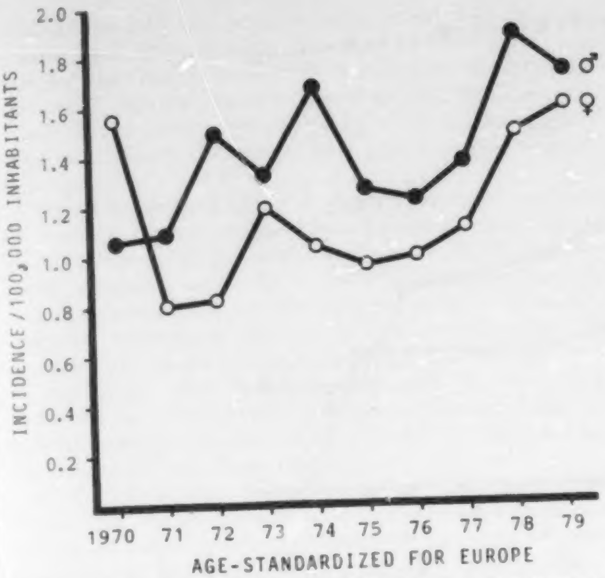
Cancer	No. of deaths (%)	
	1969	1979
Multiple myeloma	109 (13.6)	166 (15.6)
Hodgkin's disease	123 (15.4)	115 (10.8)
Non-Hodgkin's lymphomas and leukemias	568 (71.0)	783 (73.6)
Total	800 (100)	1,064 (100)



TEXT-FIGURE 1.—Age-standardized mortality rates (European standard population) for multiple myeloma, Hodgkin's disease, and other lymphoreticular cancers for the decade between 1969 and 1979.



TEXT-FIGURE 2.—Age-specific incidence rates for multiple myeloma per 100,000 male or female inhabitants of Austria in 1979 show peak incidences in the 7th and 8th decades of life.



TEXT-FIGURE 3.—Time trends of standardized incidence rates (standard population for Europe) per 100,000 male or female inhabitants of Austria between 1970 and 1979.

The frequencies of the various paraprotein types were determined in a group of 114 patients. Text-figure 5 shows that the results followed the frequency distribution pattern of normal immunoglobulins (*8*) as expected from a representative sample of multiple myeloma cases. In the total group of patients, the κ:λ ratio of 2.43:1 was comparable to that from other countries (*9–11*).

According to age at the manifestation of disease, the patients were divided into 2 groups of 65 years or younger and over 65 years, and the younger and the older age groups were compared. There was no difference with regard to the different stages of the disease at diagnosis, nor did the poor risk factors differ between either group at the threshold shown (table 2) or at other clinically relevant limits (creatinine, 1.4 mg/100 ml; calcium, 10.5 mg/100 ml; hemoglobin, 12.0 g/100 ml).

Although during the 1970's therapy of multiple myeloma was extended by the introduction of polychemotherapy regimens, at every particular point of time all patients, regardless of their age, received the same treatment. When high-dose intermittent polychemotherapy was instituted for all patients, 17 had not been treated previously, and those patients were selected to study drug tolerance. As shown in table 3, the cytostatic drug tolerance was markedly reduced in the group of older patients. After the first course of polychemotherapy, the lowest number of leukocytes was only 1,200 in the older patients compared to 4,700 in the younger ones. Considering the small sample size, the individual variations were too great to allow for a statistical confirmation of the observed differences.

Comparing the survival rates for the 2 age groups, we found that survival in younger patients was significantly ($P<0.00001$) higher than that in older ones. However, the general life expectancy of the 2 groups also differed greatly (text-fig. 6). If this fact was taken into account by the inclusion of the age group-specific death rates into the statistical evaluation, the age-related differences in survival rates vanished completely. For the younger patient group, the age group-specific expected 50% survival time of 45.4

≤65	9	5.2×10^3	2.97×10^5	12.3
>65	8	1.7×10^3	1.45×10^5	10.1

[a] Values are expressed as medians. Differences are not significant statistically.

months was matched by an observed 50% survival time of 44.7 months, and for the older patient group the equivalent values were 28.5 and 25.8 months, respectively. With strict reference to multiple myeloma, the complete survival rates of both groups could be considered identical (P=0.7).

DISCUSSION

As observed in other countries, mortality rates for multiple myeloma increased in Austria over the last decade (*12, 13*). This observation can possibly be explained by an improvement of the diagnostic facilities because medical services in Austria are covered by a social health insurance system, and the cost of more sophisticated diagnostic tests is not a limiting factor. But since it is not possible to verify the diagnostic exactness of all death certificates in the country, the question as to whether the number of myeloma cases has actually increased must remain unanswered.

The median age at diagnosis was higher than that in most other countries (*14, 15*); however, it was comparable to that reported for Sweden in 1970 (*16*) and remained stable during the observed period of time. The reason for the elevated age level could be differences in the population characteristics. A relatively large segment of the Austrian population is over 60 years old, and the total population is stagnant; i.e., the number of inhabitants remained constant, and their age distribution did not change significantly between 1969 and 1979. This and the fact that medical services are not only free and easily available but also well established and familiar to old people could account for the high median age of myeloma patients.

When the age-specific incidence rates are compared to those of other countries (*12, 17*), the figures are below the expected level. Even though notification of cancer cases is compulsory, the cancer registry has been in operation only since 1970, and complete recording of data apparently has not as yet been achieved.

In most countries the sex ratio for multiple myeloma incidence is in favor of males (*18, 19*). The same holds true for Austria, where the disease is more frequent in men than in women, but the difference is not outstandingly high.

Age-standardized incidence rates for males and females fluctuated widely during 1970–74 and showed an increasing trend and a stable male:female ratio between 1975 and 1979. The differences in the curve patterns between the early and late 1970's could be random because other published data (*12*) show variations in the same order of magnitude. Conversely, it is possible that at the very beginning of compulsory cancer registration larger centers complied more quickly and the rural population of Austria could possibly be under-represented in those figures. To avoid a possible bias, we used only the more recent data for comparison with those of other European countries. The fact that our data are comparatively recent does not influence the results, however, since a control showed that the combined figures for the decade or even the incidence rates between 1970 and 1972 would have placed Austria into the same rank.

The north-south gradient in the incidence of multiple myeloma in Europe could at least partially result from a diverse quality of diagnosis and registration. In the Scandinavian countries, especially in Sweden, extensive research and documentation have been conducted for a relatively long time, whereas in countries with a lower standard of living, e.g., Romania or Spain, the diagnostic facilities and the reporting system may be less efficient. However, the possibility of a true genetic difference in susceptibility to multiple myeloma similar to that reported for Negroes and Caucasians (*12*) cannot be ruled out.

Since no data were available on the distribution of paraprotein types in the myeloma cases documented for all of Austria, we used as a subsample multiple myeloma patients who had been diagnosed and treated at the Department of Medicine II, University of Vienna, during the relevant period of time. That patient group was very similar to the collective myeloma population of Austria in respect to age distribution and median age at diagnosis. As expected, the frequency distribution of paraprotein types as well as the κ:λ ratio of all secretory myelomas closely resembled the characteristics of normal immunoglobulins and were comparable to other published data (*20*).

Because of the generally late onset of multiple myeloma and the consequently high median age of the patients, there seemed to be an interesting opportunity to investigate the influence of age on the course of the disease. At the time of diagnosis we found no age-related differences regarding the stage of the disease and the poor risk factors. The early progression of the disease appears to be very similar in younger and older patients, and the diagnosis seems to be made at equivalent stages of tumor development. In 2 small groups of patients under identical therapy, age-dependent differences were observed in the sensitivity of bone marrow cells to cytostatic drugs. Besides an intrinsic decrease in cytostatic drug tolerance of bone marrow cells in the aged, the retarded restoration due to an age-related deficit in the hematopoietic microenvironment (*21*) could explain those results.

In accordance with the results published for the U.S. Southwest (*22*), survival rates were higher for younger patients than for patients over 65 years of age. Although this finding is statistically highly significant and clinically relevant, it does not permit the conclusion that the course of the disease is accelerated in old age. There are vast differences in the general life expectancies of the 2 age groups apart from their malignant affliction, and survival with strict regard to multiple myeloma does not show any age-related differences. While the incidence rates of multiple myeloma correlate strongly with age, the course of this cancer does not seem to be age-dependent, and the shorter survival rates of older patients can be explained by the high risk of general multiple morbidity in old age.

Generation of Suppressor Cells for Natural Killer Activity in Cancer Patients After Surgery[1,2]

Atsushi Uchida,[3] Roland Kolb,[4] *and* Michael Micksche[3]

ABSTRACT—Natural killer (NK) cell activity was examined in breast cancer patients before and after surgery, and the cells involved in the postoperative depression of cytotoxicity were characterized. NK activity against K562 target cells determined in a 4-hour ^{51}Cr release assay of blood lymphocytes from preoperative patients was comparable to that of normal donors. After surgery the patients showed a decrease in NK activity but not in number of large granular lymphocytes in the effector cell populations. When blood mononuclear cells from postoperative patients were depleted of monocytes by adherence to a serum-coated plastic dish and a Sephadex G10 column and then cultured for 24 hours, they showed an increase in NK activity. Furthermore, adherent blood cells of postoperative patients, but not of normal donors or preoperative patients, suppressed the lytic function of NK cells of normal individuals. Twenty-four-hour preculture of suppressor and effector cells was required for suppression of cytotoxicity. Neither postoperative sera nor culture supernatants of suppressor monocytes and effector cells suppressed NK activity. In contrast, the lymphoproliferative response to mitogen was not affected by surgery, and postoperative blood monocytes did not inhibit the mitogenic response of normal lymphocytes. The results suggest that the appearance of suppressor monocytes in the circulation could be one cause of depression of NK activity in postoperative cancer patients.—JNCI 1982; 68:735–741.

Lymphoid cells from normal individuals display a spontaneous cytotoxicity against a variety of tumor cells and some normal target cells (*1, 2*). The effector cells are designated NK cells and are thought to play an important role in host resistance against tumors, virus-infected cells, and microbes (*1*). Recently, human NK cell activity has been demonstrated to be exerted by a morphologic subpopulation of lymphoid cells, LGL (*3, 4*), although the proportion of active NK cells among LGL is not yet determined.

It has been demonstrated that NK activity is depressed in tumor-bearing animals (*5*). Pronounced reduction of NK activity is documented in patients with advanced cancer (*6, 7*) but not in patients with regionally-locally controlled tumors (*8*). The existence of cells and factors regulating the level of NK activity both in vivo and in vitro is suggested by experimental evidence: Interferon enhances the activity of NK cells (*9, 10*). Prostaglandins have both an inhibitory effect (*11, 12*) and a stimulatory effect on NK cells (*12*). NK activity of mouse spleen cells can be suppressed by spleen cells of mice exhibiting low cytotoxicity as the result of young age or of experimental treatments (*13–16*). In humans, carcinomatous pleural effusions are found to contain suppressor monocyte–macrophages, which could be one cause of the lack of NK activity in the effusion of cancer patients (*17*).

Trauma is often accompanied by a loss of immunocompetency. Shortly after major surgery, patients were found to have impaired cell-mediated immunity, such as anergy to skin test antigens (*18*) and depression of lymphoproliferative response to mitogens and antigens (*19*). Recently, suppressor cells were demonstrated to be responsible for the depression of mitogenic response after thermal injury (*20*) and of mixed lymphocyte reactions after surgical trauma (*21*). In addition, the incidence of tumor take and spontaneous metastases has been shown to increase when tumor-injected animals are subjected to surgery (*22*).

NK cells seem to be more effective in dealing with a small number of tumor cells than in dealing with a large tumor cell load (*1*). Recent evidence in experimental animal models has suggested that NK cells are important in host defense against circulating tumor cells and therefore can prevent the development of tumor cells into metastases (*23–27*). It is important to know whether the level of NK activity is depressed in cancer patients after surgery, since surgical manipulation of cancer patients is known to result in an abrupt appearance of malignant cells in the circulation and an increased incidence of tumor metastases (*28, 29*). The present study was designed to investigate the effect of surgery on NK activity (especially its regulatory mechanism) of patients with breast cancer.

MATERIALS AND METHODS

Patients.—Peripheral blood was obtained from 21 patients with breast carcinoma of stage I or II. The patients, ranging in age from 30 to 65 years, had never been given any anticancer agent at the time of the study. All patients underwent modified radical mastectomy including prophylactic lymph node dissection. Controls were peripheral blood specimens from 21 healthy females whose ages were roughly matched with those of the patients.

Cell preparation and separation.—Effector cells were prepared as described elsewhere (*7, 17, 30*). Lymphocyte-rich mononuclear cells were isolated from heparinized peripheral blood by centrifugation on a Ficoll–Hypaque gradient (sp gr, 1.077; Nyegaard & Co., Oslo, Norway). The cells in the interface were collected, washed, and resuspended in RPMI-1640 tissue culture medium supplemented with 25 m*M* HEPES,[5] 2 m*M* L-glutamine, 100 U penicillin/ml, 100 μg

streptomycin/ml, and 10% heat-inactivated FCS (Gibco Biocult, Glasgow, Scotland) (referred to as "complete medium"). The mononuclear cells were then incubated in a 75-cm^2 plastic dish (Falcon Plastics, Oxnard, Calif.), which had been coated overnight with heat-inactivated FCS, for 60 minutes at 37°C. After incubation, the nonadherent cell suspensions were removed and the dish was washed three times with cold medium. The adherent cells were then removed from the dish by incubation for 15 minutes at 4°C with phosphate-buffered saline containing 0.2% EDTA and 5% heat-inactivated FCS and by vigorous washing with a pipette. They were then resuspended in complete medium. The recovery of the adherent cells containing more than 93% monocytes as judged by nonspecific esterase staining and morphology was 5-10% for normal donors and 10-15% for preoperative and postoperative cancer patients of the original number of cells placed on the dish. This fraction is hereafter referred to as "monocytes." The nonadherent cells were washed, resuspended in complete medium, and passed through a Sephadex G10 column to remove further contaminating monocytes. The recovery of the G10-nonadherent cells containing more than 99% lymphocytes as judged by nonspecific esterase staining and morphology was 65-90% of the original input. The fraction is hereafter referred to as "lymphocytes." Every fraction was more than 95% viable according to trypan blue dye exclusion.

Target cells.—The K562 human myeloid leukemia cell line (*31*) was used as targets as previously described (*7, 17*). Target cells were labeled by addition of 100 μCi $Na_2{}^{51}CrO_4$ (sp act, 100-350 μCi/μg Cr; Radiochemical Centre, Amersham, Buckinghamshire, England), incubated for 1 hour at 37°C, washed, and resuspended at a concentration of 1×10^5/ml in complete medium.

Cytotoxicity assay.—A 4-hour ^{51}Cr release assay was performed as described elsewhere (*7, 17*). We added 100 μl labeled target cells (1×10^4) and 100 μl effector cells at different numbers to wells of round-bottomed microtiter plates (Linbro Scientific Inc., New Haven, Conn.). Each plate was centrifuged and incubated for 4 hours at 37°C in a humidified atmosphere of 5% CO_2 in air. Samples were harvested by the transfer of 100 μl of supernatant from each well to vials, and the activity was counted in an auto-gamma scintillation counter. Spontaneous ^{51}Cr release was determined in wells containing target cells and medium, and maximum release was determined by addition of Triton X-100. The percentage of cytotoxicity for each assay was calculated by the following formula for triplicate samples: Percent cytotoxicity=[(experimental release − spontaneous release)/(maximum release − spontaneous release)]×100. The ranges of spontaneous and maximum release were 3-12% and 80-95% of the total isotope count added, respectively.

Suppressor assay for NK activity.—Effector cells at a concentration of 1×10^6/ml in complete medium were precultured for 24 hours in a 17×100-mm plastic tube (Falcon Plastics) in a humidified atmosphere of 5% CO_2 in air in the presence or absence of different numbers of cells used as suppressors as previously described (*17*). After culture, the tube was centrifuged at 200×*g* for 10 minutes, and the supernatant was removed and stored at −70°C. The cells were washed three times, resuspended in complete medium, and tested for cytotoxicity as described above. Inhibition of cytotoxicity was expressed as the percentage of suppression obtained from the following formula: Percent suppression=[1−(percent cytotoxicity in the presence of suppressor cells)/(percent cytotoxicity in the absence of suppressor cells)]×100.

Proliferative response to mitogen.—Mononuclear cells (1×10^5) were cultured in 200 μl complete medium in microtiter culture wells (Falcon Plastics) with an optimal dose of 15 μg PHA-P/ml (Difco Laboratories, Detroit, Mich.) and 5×10^{-5} *M* 2-mercaptoethanol for 72 hours in a humidified 5% CO_2 atmosphere (*17, 30*). Then 1 μCi [^{3}H]thymidine (5 Ci/mmol; Radiochemical Centre) was added to each well for the last 6 hours of the culture, and the incorporation of thymidine into DNA was measured in a liquid scintillation counter. Results were expressed as mean Δcpm in triplicate wells, where Δcpm was the difference between the cpm of stimulated and unstimulated cultures.

Suppressor assay for mitogenic response.—Monocytes (2×10^4) in 100 μl complete medium were mixed with the same volume of 1×10^5 responding cells and cocultured as described above. Inhibition of proliferative response to mitogen was expressed as the percentage of suppression obtained from the following formula: Percent suppression=[1−(Δcpm in the presence of suppressor cells)/(Δcpm in the absence of suppressor cells)]×100.

Statistical analysis.—The results were evaluated for statistical significance by Student's *t*-test.

RESULTS

Cytotoxicity against K562 cells of peripheral blood mononuclear cells of patients with stage I or II breast cancer was comparable to that of age-matched normal donors (table 1). At 1-2 weeks after surgery, blood mononuclear cells of cancer patients showed a decrease in cytotoxicity at effector-to-target cell ratios of 10:1-40:1. Significant reduction of NK activity was observed in 16 of 21 patients after surgery and was not related to the stage of disease and length of anesthesia administration (data not shown). Kinetic studies showed that the depression of cytotoxicity in cancer patients became noticeable 2-3 days after surgery and lasted over 2 weeks, while normal donors tested on the same day that patients were tested showed relatively constant levels of NK

activity (daily variance being usually <10% cytotoxicity) (data not shown). In contrast, no significant differences were observed in the frequency of LGL in blood lymphocytes of normal individuals and preoperative and postoperative cancer patients. The number of LGL-binding K562 cells was also not affected by surgery (data not shown). While the NK cells are not synonymous with or equivalent in number to LGL, up to 70% of LGL have been demonstrated to be able to function as NK cells against highly sensitive target cells (Herberman RB: Personal communication). These results suggest that surgery may be followed by a reduction in the lytic activity but not in the number of NK cells in the peripheral blood of cancer patients.

However, no significant differences were seen in lymphoproliferative responses to PHA-P of normal donors and cancer patients before and 7–14 days after surgery.

For the detection of cells involved in the depression of NK activity in postoperative cancer patients, blood mononuclear cells were depleted of monocytes by adherence to a serum-coated plastic dish and a Sephadex G10 column. The mere removal of monocytes caused no enhancement of cytotoxicity against K562 cells (table 2). When these monocyte-depleted cells from postoperative patients were cultured for 24 hours in complete medium, they showed a significant increase in NK activity. In contrast, blood mononuclear cells of preoperative patients and normal individuals showed no such increase. The removal of monocytes from 24-hour-cultured mononuclear cells resulted in no increase in cytotoxicity. These results suggest that the peripheral blood of postoperative cancer patients contains potentially cytotoxic cells, which are functionally suppressed by monocytes and can recover their lytic function after a 24-hour in vitro culture in the absence of suppressor monocytes.

For confirmation of the above suggestion, functional

[a] Normal lymphocytes were preincubated for 24 hr with or without 20% postoperative monocytes, either at 4°C or 37°C, washed, and tested for cytotoxicity against K562 cells at a lymphocyte-to-target cell ratio of 20:1.

[b] −, monocytes were not added, no suppressor cells were present; +, monocytes were added.

[c] Value is significant ($P<0.05$).

TABLE 5.—*Effects of serum and supernatants of monocyte culture on NK activity*[a]

Expt No.	Percent cytotoxicity against K562 cells of lymphocytes cultured with:				
	Medium	Monocytes	Serum	Monocyte culture supernatants	Monocyte-lymphocyte culture supernatants
1	41	15[b]	39	43	37
2	62	36[b]	56	59	61
3	59	26[b]	61	56	55
4	72	47[b]	68	71	69
5	36	20[b]	37	32	35
6	51	34[b]	47	53	48

[a] Normal blood lymphocytes were precultured for 24 hr with 20% monocytes, 20% serum, or 24-hr culture supernatants of monocytes with or without lymphocytes from postoperative patients, then washed, and tested for cytotoxicity at an effector-to-target cell ratio of 20:1.

[b] Value is significantly lower compared to that in other groups ($P<0.05$).

blood NK cells of normal controls were precultured for 24 hours with or without blood monocytes of postoperative patients showing a reduction of NK activity after surgery, then washed, and tested. As previously reported (*17, 32*), NK activity and compositions of 24-hour-cultured mononuclear cells were similar to those of freshly drawn cells (data not shown). Results of a representative experiment are shown in table 3. Blood monocytes did not lyse K562 cells in this assay (data not shown). NK activity of normal lymphocytes was suppressed by postoperative blood monocytes, whereas monocytes from preoperative patients or normal donors did not inhibit cytotoxicity. Monocyte-mediated suppression of NK activity was noticeable at a suppressor-to-effector cell ratio of 0.1:1 and peaked at 0.2:1–1:1. The recovery of viable cells cocultured with monocytes was comparable to that of viable cells cultured alone (data not shown), indicating that monocytes are not toxic to lymphocytes. Significant suppression of NK activity of normal lymphocytes by postoperative monocytes was observed at a suppressor-to-effector ratio of 0.2:1 in 12 of 16 patients showing postoperative reduction of NK activity (text-fig. 1). In contrast, blood monocytes of postoperative patients showing no depressed NK activity after surgery did not inhibit cytotoxicity (data not shown).

To ascertain whether the preculture of suppressor monocytes and NK cells is required for the suppression of NK activity, we tested postoperative monocytes for the activity suppressing the lytic function of NK cells with or without preincubation with fivefold the number of normal lymphocytes for 24 hours either at 4°C or 37°C. The addition of monocytes to a mixture of effector and target cells did not inhibit NK activity (table 4). Preincubation of normal lymphocytes with postoperative monocytes for 24 hours at 37°C suppressed cytotoxicity, whereas preincubation at 4°C did not. The presence of 24-hour-cultured monocytes only during a cytotoxicity assay also gave no inhibition of NK activity (data not shown). The results suggest that 24-hour contact of suppressor monocytes and NK effector cells prior to a cytotoxicity assay is necessary for suppression of NK activity.

The possibility that suppressor substances are secreted by suppressor monocytes was examined. Normal lymphocytes were precultured for 24 hours in complete medium, postoperative sera, supernatants produced by 24-hour cultures of postoperative monocytes, or supernatants from 24-hour cultures of postoperative monocytes and normal lymphocytes. They were then washed and tested for NK activity. Neither culture supernatant nor serum suppressed NK activity, whereas monocytes did suppress cytotoxicity (table 5). The presence of indomethacin, an inhibitor of prostaglandin synthesis, during the preculture and cytotoxicity assay failed to abrogate the monocyte-mediated suppression of NK activity (data not shown). The results suggest that suppressor–effector cell interaction is necessary for the suppression of NK activity.

So that we could ascertain whether postoperative blood monocytes suppress the mitogenic response, normal lymphocytes were stimulated with PHA-P in the presence or absence of postoperative monocytes. Monocytes did not inhibit lymphoproliferative response, whereas they suppressed NK activity (table 6). Increasing numbers of monocytes also failed to inhibit mitogenic response (data not shown).

TABLE 6.—*Effects of monocytes from postoperative patients on PHA-P response and NK activity*[a]

Expt No.	[^{3}H]thymidine incorporation in response to PHA-P, Δcpm[b]		Percent suppression	Percent cytotoxicity against K562 cells at effector-to-target cell ratio of 20:1		Percent suppression
	Normal lymphocytes	Postoperative monocytes added		Normal lymphocytes	Postoperative monocytes added	
1	52,083±3,947	48,451±3,656	7	62	36	42[c]
2	36,820±815	37,926±746	−3	52	14	75[c]

4	62,037±3,593	56,734±2,914	9	39	11	69[c]
5	43,949±1,658	46,503±2,715	−6	59	26	53[c]

[a] Lymphocyte-rich mononuclear cells from normal individuals were tested for mitogenic response and NK activity in the presence or absence of 20% monocytes from postoperative cancer patients.

[b] Results are expressed as means ± SD.

[c] Value is significant ($P<0.05$).

DISCUSSION

The present study has demonstrated that the activity of NK cells decreases after removal of tumors from patients with stage I or II breast cancer. The findings are of practical interest, since evidence is increasing that NK cells may play an important role in host resistance against circulating tumor cells and therefore inhibit the development of tumor cells into metastases: In mice with high NK activity, iv injected tumor cells are rapidly eliminated (*33*). A close correlation is demonstrated between levels of host natural cytotoxicity and/or NK activity and capacity to eliminate blood-borne tumor cells (*24*). Low NK activity was associated with increased incidence of metastases in 3-week-old nude mice (*25*). Tumor cells modified to be sensitive to NK lysis by in vitro culture demonstrated in vivo an increased growth rate, faster induction time, and an increased metastatic capability in beige mice showing impaired NK activity compared to the NK activity in control mice (*26, 27*). In addition, surgical manipulation of cancer patients is known to result in an abrupt appearance of tumor cells in the circulation of these patients and to be correlated with an increased incidence of metastases (*28, 29*). Our findings of the postoperative reduction in NK activity in cancer patients could be one mechanism by which tumor metastases are enhanced after surgery. The findings, however, somewhat differ from other observations that after surgery NK activity specifically directed toward melanoma cells increased in patients with stage I malignant melanoma but decreased in patients with stage II malignant melanoma (*34*). The discrepancy may be explained by differences in the disease, surgical procedure, and cytotoxicity assay.

One mechanism of the lack of NK activity has been shown to be the presence of suppressor cells in the spleens of *Corynebacterium parvum*-injected, bone marrow-tolerant, infant, carrageenan-treated, hydrocortisone-treated, or adriamycin-treated mice (*13–16*). NK suppressor cells induced by hydrocortisone or carrageenan were found to be macrophage-like, and those from infant or irradiated mice were found to be null cells (*14*). We have found that blood monocytes from postoperative cancer patients can suppress the activity of functional NK cells and are responsible for the depression of NK activity in these patients. The findings are in agreement with those of previous reports that adherent blood cells of some cancer patients (*35*) or monocyte–macrophages of malignant pleural effusions of lung cancer patients (*17*) have suppressor activity for NK cells.

The mechanism by which suppressor cells inhibit NK activity is not clear. The present study demonstrates that 24-hour contact of suppressor monocytes and NK effector cells is required for suppression of NK activity. This observation is in contrast with that of other reports that suppression results from the mere addition of suppressor cells to a mixture of effector and target cells in mouse models (*14*) but is in keeping with our previous findings in humans (*17*) and the findings of others in mice (*36*) of a requirement for prolonged contact of suppressor and effector cells prior to a cytotoxicity assay. It has been shown that 24-hour culture of lymphocytes results in induction of interferon and enhancement of NK activity (*37*). However, it seems unlikely that postoperative monocytes inhibit culture-induced activation of NK cells rather than suppress NK activity, since no significant difference was observed in NK activities of fresh and 24-hour-cultured lymphocytes and culture supernatants contained no detectable amount of interferon (data not shown), as previously observed (*17, 32*). These differing results may be based on the method of culture.

There is evidence that suppressor substances are involved in the suppression of NK activity. Sera from mice contain inhibitors of both NK activity and antibody-dependent cellular cytotoxicity (*38*). Culture supernatants of suppressor cells from hydrocortisone-treated mouse spleens inhibit NK activity (*39*). NK activity is suppressed by prostaglandins (*11, 12*). In contrast, blood monocytes from postoperative cancer patients suppressed NK activity by direct interaction with NK cells and independently of prostaglandin induction. Our findings confirm those of previous reports that suppression of NK activity by adherent cells from the peripheral blood (*35*) and pleural effusions (*17*) of cancer patients is not lowered by indomethacin.

We have demonstrated that functionally suppressed NK cells can recover their lytic function when these cells are first depleted of suppressor monocytes and then cultured for 24 hours. The mere removal of monocytes from blood mononuclear cells caused no enhancement of NK activity. This observation is in agreement with the findings of others (*40*) and with our previous observations (*7, 17, 32*) but differs from the observation in another report (*41*) that NK activity is enhanced after the removal of adherent cells. Possibly, the discrepancy is based on the details of removal of monocytes.

In the present study, cancer patients 7-14 days after surgery showed no decrease in lymphoproliferative response to mitogen, and their blood monocytes did not suppress mitogenic response. However, some patients tested on the 2d postoperative day showed depression of mitogen reactivity but had no mitogenic suppressor cells in their circulation (data not shown).

Why suppressor monocytes appear in the circulation of cancer patients after surgery is not clarified in the present study. Neither depression of NK activity nor development of NK suppressor cells was observed in patients with nonneoplastic disease after surgery or in cancer patients who received extensive anesthesia but did not have their tumors removed (Uchida A: Manuscript in preparation). Possibly suppressor monocytes are released from the tumor site at the time of surgical resection, since surgical manipulation of cancer patients is known to result in an abrupt appearance of viable tumor cells in the peripheral blood (*28*). Further studies on the regulatory function of monocytes within the site of breast tumors may support the above suggestion.

Measurement of Cancer Incidence in the United States: Sources and Uses of Data[1,2]

E. Robert Greenberg, *M.D.*,[3] Theodore Colton, *Sc.D.*,[4] *and* Curtis Bagne, *Ph.D.*[5,6]

ABSTRACT—Since 1937, investigators have compiled a vast amount of information on cancer incidence in the United States. Three national cancer surveys were conducted in 1937, 1947, and 1969–71; each used somewhat different methods but covered populations who overlapped greatly. Concurrently, population-based tumor registries were developed that were capable of measuring cancer incidence. Since 1973, the Surveillance, Epidemiology, and End Results Program, an amalgam of such registries, has generated cancer incidence data for the United States. Available data provide a rough measure of the size of the cancer problem and may help those who direct prevention programs and those who plan studies of cancer etiology. Because the completeness and validity of existing incidence data are not known with certainty, comparisons among these incidence rates require cautious interpretation.—JNCI 1982; 68:743–750.

The rate of cancer occurrence receives extraordinary attention in the United States. Witness, for example, the controversy that erupted after publication of an article claiming that the U.S. cancer incidence may be increasing (*1*). The article received coverage on the television evening news, became the subject of debate in Congress, and was cited by the White House Council on Environmental Quality as evidence that factors causing cancer are on the increase and that chemical carcinogens may require tighter regulations (*2*). Subsequently, a number of epidemiologists and other scientists strongly objected to the methods of analysis and the conclusions of the article (*3, 4*). The controversy pointed out the great importance placed on cancer incidence figures by elected officials and by the general public.

Scientists working in cancer research often have reason to cite cancer incidence rates. Many scientists, however, seem unaware of how these rates are generated, their validity, and their proper interpretation. In this paper, we review the sources of U.S. cancer incidence information and indicate some of the uses and limitations of these data. The basis for the paper is a 2-year study that we and our colleagues conducted to evaluate current and potential methods of determining cancer incidence in the United States. The detailed reports of the evaluation are available from the National Technical Information Service (*5, 6*).

HISTORICAL BACKGROUND: THE NATIONAL CANCER SURVEYS

Until the late 1930's there were no sources of cancer incidence data for the U.S. population. Mortality figures provided the only population-based information on cancer occurrence, and these, supplemented with reports of hospital case series, were used to support estimates of the scope of the cancer problem. In fact, the literature of that era reveals little concern with the rate of new cancer occurrence in the population, i.e., cancer incidence. The proportion of the population affected with cancer, i.e., cancer prevalence, was used as an indicator of the burden of cancer morbidity and appears to have been of greater initial interest than incidence. The first large survey done by the NCI reflected this concern with existing rather than new cancer cases.

Begun in 1937, the study covered 10 metropolitan areas (Atlanta, Ga.; Birmingham, Ala.; Chicago, Ill.; Dallas–Fort Worth, Tex.; Denver, Colo.; Detroit, Mich.; New Orleans, La.; Philadelphia, Pa.; Pittsburgh, Pa.; and San Francisco, Calif.) and included a population of 13 million, roughly 10% of the total U.S. population. Areas were chosen so that the distribution of the population among three regions—the North, the South, and the West—was proportionate to that of all cities of 100,000 population or larger. They were not meant to be representative of the U.S. population but were, instead, restricted to metropolitan regions with a central city population of more than 100,000 where one could expect better diagnostic information and greater cooperation of the local medical community (*7*).

The NCI staff surveyed each area for 1 year (either 1937, 1938, or 1939) and tried to identify all existing and newly diagnosed cases of cancer (except for leukemia and Hodgkin's disease) and to obtain detailed medical data for each case. The notion of using household interview surveys was rejected because cancer patients and their families seemed unable to give accurate information on primary site, histology, and other clinical information. Further, an appreciable number of persons at that time were not aware that their physicians had diagnosed a cancer in them or, if they knew, might not be willing to disclose this information. The NCI investigators thus chose to survey sources of medical care as a way to identify cancer cases and to obtain more reliable and comprehensive clinical information.

All physicians, hospitals, and clinics in the area received, by mail, forms that requested information on each cancer

[6] We gratefully acknowledge the assistance of members of the NCI Biometry Branch and of personnel with the Surveillance, Epidemiology, and End Results Program registries, many of whom helped us gather information. Susan Vogt and Emily Fayen participated in the original evaluation. Philip Cole, Dwight Janerich, and O. Ross McIntyre provided helpful suggestions to us while we were writing the manuscript.

patient including name, date of diagnosis, type of treatment, current vital status, and method of confirmation of diagnosis. If requested, the field staff visited physicians' offices to abstract the required data. Physicians who did not return their forms promptly were contacted directly; only about 2% of physicians refused to participate. Staff also searched death certificates to identify cancer deaths and check the completeness of case finding.

Initial reports from this first survey, commonly called the Ten Cities Survey of 1937, focused on the mortality and prevalence of cancer in each area, as well as percent distributions of cases (both residents and nonresidents of the areas) by primary site, race, and sex. Incident cases were reported in terms of new cases per reported death, or when actual incidence rates were cited, the crude rates were reported (*8–17*). In 1944 and again in 1949, Dorn (*18*, *19*) summarized the survey findings by presenting age-, race-, sex-, and site-specific incidence rates.

The second national survey occurred in 1947–48 and covered the same 10 metropolitan areas (with the exception of Fort Worth). Similar methods of case identification and data collection were used, but attention was focused on incident, resident cases. This time leukemia and Hodgkin's disease were included. Results from the survey, after adjustment for inclusion and coding discrepancies to make them consistent with those of the earlier survey, were published in another series of reports (*20–29*). A final summary report described variations in cancer incidence by age, sex, race, geographic region, marital status, and primary site. It also reported intercity variations, trends in cancer morbidity, associations of cancer incidence with income class, stage of disease at diagnosis, comparison of death certificates with case reports, and interpretation of the age-incidence curve (*7*).

The populations studied in the two Ten Cities Surveys were not highly representative of the total U.S. population with regard to cancer occurrence. In 1950, for example, cancer mortality for the populations covered in the Ten Cities Survey was about 10% higher than that for the total U.S. population (*30*) and indicated that cancer occurred less frequently in rural areas. This notion was supported by a survey in the rural state of Iowa.

The Iowa study of 1950 employed the same techniques as those used in the Ten Cities Surveys. Only 6.8% of the population of Iowa at that time lived in cities of 100,000 or more. Comparison of age-adjusted incidence rates for Iowa with those for the 10 metropolitan areas showed Iowa to have cancer rates 14% lower for males and 8% lower for females. Checks on internal consistency and comparison with mortality figures indicated that the lower incidence rates were real and not explained by selective migration of ill persons to urban areas or by differences in diagnostic levels (*31*).

Twenty-one years elapsed between completion of the second Ten Cities Survey and the TNCS of 1969–71. The organizers of the TNCS wished to assess trends in cancer morbidity from 1937 to 1971 and to achieve broader coverage of the U.S. population. Seven of the original 10 cities continued in the TNCS. Coverage of six of these was enlarged to include entire standard metropolitan statistical areas as defined by the U.S. Department of Commerce. The staff surveyed the entire State of Colorado, instead of Denver alone. Addition of Iowa increased coverage of the rural and farm population and permitted comparison with the 1950 results. Chicago, included in the original studies, was replaced by another northern metropolitan area, Minneapolis–St. Paul, Minn. Philadephia was not resurveyed because of administrative difficulties, and, in New Orleans, the medical community did not seem receptive to a survey by a Federal Agency.

Data collection methods used in the TNCS differed from those of past surveys. Rather than relying on direct reporting by physicians, TNCS field staff visited hospitals, clinics, radiation therapy centers, pathology laboratories, and physicians' offices to abstract the needed information directly from patient records. To maximize data completeness and accuracy, staff searched multiple sources for missed cases and used rigorous quality-control procedures.

The staff of the TNCS found information on 181,027 new cases of cancer among residents of the survey areas. A summary report on the TNCS presented variation of incidence rates by race, by sex, and for different primary sites and histologic types (*32*). A series of advanced reports gave incidence data for the individual survey areas (*33–42*). An analysis of trends in cancer incidence from 1937 to 1969 was published and took into some account the changes in the covered geographic areas (*43*). Data on hospitalization and payments to hospitals were also reported (*44*), as were detailed analyses of incidence rates for individual anatomic sites (*45–49*).

INDIVIDUAL TUMOR REGISTRIES

Independent of the conduct of the three national cancer surveys, local population-based tumor registries developed and proliferated. New York State began an incidence-reporting registry in 1940 (*50*), and Connecticut organized its registry in 1941 with data complete back to 1935 (*51*). These two registries became the reference points for U.S. cancer incidence data during the interval between the national surveys of 1947 and 1969–71.

Many other large tumor registries arose during the 1950's, often by amalgamation of local hospital registries. Their general purpose was to monitor cancer treatment and outcome with the intent of improving patient care. A number of these registries joined in 1956 into the EREP, which measured survival of cancer patients (*52*). Because some of the registries in EREP covered all the hospitals in a defined geographic area, they were also used to generate incidence data. Additional population-based registries sprang up under the Regional Medical Program in the 1960's, again with the purpose of improving medical care. Data from several of these registries were published in the three editions of "Cancer Incidence in Five Continents" (*53–55*) and were used to compare incidence rates among distinct geographic areas in the United States and other countries.

THE SEER PROGRAM

The National Cancer Act of 1971 became law days before the end of the reporting period for the TNCS. The political activity and hearings around this legislation emphasized the need for statistics to plan and evaluate the expanding cancer program and called into question the adequacy of the ad hoc National Cancer Surveys.

Even before the TNCS had commenced, NCI officials had decided that it would be the last survey of its kind in the United States. A major drawback to the periodic morbidity survey was the extensive time required to plan the survey, secure the cooperation of the medical communities, and recruit and train staff. When to this planning and start-up time was added the 3-year reporting period plus another year or 2 for analysis and dismantling of the survey, it became clear that a series of decennial surveys would require nearly continuous effort. Also, a continuous registry system appeared capable of providing the survival data then obtained from the EREP (*56*).

In 1971 NCI appointed an Ad Hoc Advisory Committee on Population-Based Epidemiology Research Centers to assess the potential contributions of participants in the TNCS and the EREP to a broadened program of cancer epidemiology. In its report the Committee affirmed a need for cancer incidence data and recommended that NCI "develop a coordinated program of cancer surveillance, descriptive epidemiology and end-results evaluation." It stated, however, that "NCI research and program goals do not presently require, or even suggest an ultimate need for, the establishment of a large scale, broadly-based national program of cancer registration" (*57*).

In 1973 the NCI established the SEER Program. SEER initially included eight population-based tumor registries that had participated in either the TNCS or the EREP or in both. The program now includes nine registries in the United States and one in Puerto Rico; each registry determines the incidence of cancer and the survival of all cancer patients resident within its geographic bounds. The basis for the selection of participant registries has been their demonstrated ability to operate and maintain a population-based cancer-reporting system and the unique population subgroups that they cover (*58*).

The nine U.S. registries cover a population of about 20 million individuals located in diverse areas of the country (table 1). Each registry annually reports every new case of disease that meets criteria for patient residence and date of diagnosis.

The SEER data set consists primarily of demographic and follow-up information about the patient, and a description of the neoplasm and is presented below:

- Basic identification:
  - SEER participant
  - Case No. and check digit
  - Type of reporting source
- Demographic information:
  - Place of residence at diagnosis
  - Residence summary
  - Place of birth
  - Year of birth
  - Age at diagnosis
  - Race-ethnicity
  - Sex
  - Marital status at diagnosis
- Description of this neoplasm:
  - Date of diagnosis
  - Sequence No.
  - Primary site
  - Laterality
  - Multiplicity within primary site
  - Histologic type
  - Diagnostic confirmation
  - Extent of disease
- Therapy:
  - Date cancer-directed therapy started
  - First course of cancer-directed therapy

TABLE 1.—*SEER Program registries in the United States*

Registry	Year of first reporting	Reporting area	Land area, square mile	Population,[a] $\times 10^3$	Population density, per square mile
San Francisco–Oakland, Calif.	1973	5 counties (Alameda, Contra Costa, Marin, San Francisco, and San Mateo)	2,480	3,110	1,254
Connecticut	1973	Entire state	4,862	3,032	624
Atlanta, Ga.	1976	5 counties (Clayton, Cobb, De Kalb, Fulton, and Gwinnett)[b]	1,728	1,390	812
Hawaii	1973	Entire state	6,425	769	120
Iowa	1973	Entire state	55,941	2,824	51
New Orleans, La.[c]	1974	3 parishes (Jefferson, Orleans, and St. Bernard)	1,080	982	909
Detroit, Mich.	1973	3 counties (Macomb, Oakland, and Wayne)	1,952	4,200	2,152
New Mexico[d]	1973	Entire state	121,412	1,016	8
Utah	1973	Entire state	82,096	1,059	13
Seattle, Wash.	1974	13 counties (Clallam, Grays Harbor, Island, Jefferson, King, Kitsap, Mason, Pierce, San Juan, Skagit, Snohomish, Thurston, and Whatcom)	17,691	2,303	130

[a] Based on 1970 Census of the Population.

[b] Ten rural counties added with data back to 1978: Glascock, Greene, Hancock, Jasper, Jefferson, Morgan, Putnam, Taliaferro, Warren, and Washington.

[c] Withdrawn from the program in 1981. Last data were from 1978.

[d] The New Mexico Registry also collects data from the predominantly Indian population of Northwestern Arizona.

Follow-up information:
- Date of last follow-up or of death
- Follow-up status
- Cause of death
- International Classification of Diseases code used for cause of death

Information on environmental and occupational exposures and family histories is not included because it is not reliably documented in the medical records that serve as the basis for case reporting. Names of patients, hospitals, and physicians are not identified in data submitted to NCI to help maintain the privacy of individuals.

Registry staff identify cases primarily through searches of hospital discharge lists, pathology report forms, and radiation therapy records. The approach to searching for cases varies among registries. Most registries use their employees to perform this task, but some, such as the one in Connecticut, rely on employees of the local hospitals to find cases. In several states, but not all, state law or health department regulation requires physicians and hospitals to report new cases of cancer to the registry.

In 1978 the SEER Program published its first report on cancer incidence covering 1973–76. The data consisted of age-adjusted rates for 20 common cancer sites, presented by year of diagnosis, race, sex, and tumor registry area (*58*). The SEER Program has also published detailed age-, sex-, and race-specific cancer incidence figures for each registry for 1973–77 (*59*).

ASSESSING THE QUALITY OF REPORTED DATA

Despite the abundance of reported cancer incidence data for the United States, only limited information exists on the validity of these figures, largely because there have been no standards against which a particular set of incidence data could be compared to determine its completeness and diagnostic accuracy. There are, however, three figures that may serve as crude indicators of data quality. These are the proportion of cases known by DCO, the percent MC, and the proportion of cases with NSD. The DCO figures indicate completeness of registration. The MC and NSD figures indicate the accuracy of diagnostic information.

The DCO figure is the proportion of registered cases for which the only information about the diagnosis of cancer comes from a death certificate. Two types of patients contribute to this figure: 1) patients, such as those not hospitalized, for whom death certificates provide the only documentation of cancer and 2) deceased patients whose cancer diagnosis is recorded in a medical record that has been overlooked by the case-finding personnel of the registry. When a case of cancer is identified through review of death certificates, registry staff usually contact the certifying physician or hospital where death occurred to obtain records with additional diagnostic information. Only if none are found does the case count as DCO. Thus a low DCO figure may indicate thorough follow-back of information in addition to complete case finding.

Completeness of registration and the DCO figure partly depend on the way cancer patients obtain medical care. Those who receive all their care in out-of-state hospitals (which often are not covered by a registry) are not reported as cases unless they die and have a cancer noted on the death certificate. Those who lack ready access to medical care may suffer with undiagnosed cancer until it, or another condition, causes their death. Increased accessibility and use of medical care thus will result in more cases reported and a lower DCO figure. The elderly, in particular, have had a substantial increase in their use of medical services since the mid-1960's. As a result, one might expect more of their cancers to be diagnosed and reported. In part because of these reasons, some authors recommend that data on people over 65 should be excluded from analyses of temporal trends in cancer incidence and mortality (*4*, *60*).

The proportion of cases for whom cancer has been histologically or cytologically confirmed makes up the MC measure and reflects the accuracy of diagnostic information in the registry. For primary cancer arising in the liver, pancreas, brain, or other inaccessible organs, an MC diagnosis provides reassurance that cancer is actually present and that it is primary and not metastatic to these sites. Of course, microscopic confirmation reflects not only the quality of diagnostic information but also the accessibility of medical services.

The NSD figure is the proportion of cases reported as primary cancers of the liver, bone, and "other or unspecified" sites. In the United States, primary cancers of the liver and bones are rare, although metastases to these sites are frequent. Some patients initially thought to have cancers arising in the liver or bone will, on closer study, be found to have cancers that have metastasized to these organs. Similarly, cancers of unknown or unspecified primary sites will be seen more frequently when diagnostic searches are less vigorous. The NSD measure is not a good indicator of data quality for purposes of comparing data from the United States with those from different countries, because in many countries primary liver cancer is much more common than it is in the United States.

Table 2 lists these three indicators of data completeness and quality for the three national cancer surveys and for the SEER Program (1973–77). The DCO proportion has decreased from nearly 16% in the first Ten Cities Survey to 1.4% in the SEER Program (range 1.0–3.0% for the U.S. registries) (*59*). As noted above, the lower DCO figures for recent data partly reflect greater access to care by the elderly and vigorous follow-back of death certificates in addition to improved case finding. The percent of MC tumors has increased to a high of 92.2% (range, 88.9–96.8%) in the

TABLE 2.—*Indicators of validity for major U.S. cancer incidence data sources*

Source	DCO, %[a]	MC, %[b]	NSD, %[c]
Ten Cities Survey of 1937–39[d]	15.9	63.9[e]	NA[f]
Ten Cities Survey of 1947–48	13.6	64.7	7.3
TNCS of 1969–71	2.1	90.1	4.5
SEER Program of 1973–77	1.4	92.2	4.5

[a] Percent of all cases with information only from a death certificate.

[b] Percent of all cases histologically or cytologically confirmed.

[c] Percent of all cases classed as bone, liver, or "other and unspecified" primary sites.

[d] Leukemia and Hodgkin's disease were not included.

[e] Estimate based on data in (*6*) (includes skin cancers).

[f] Data not available.

SEER Program, whereas the proportion of tumors in the liver, brain, and other and unspecified categories has declined from 7.3% in 1947-48 to 4.5% now. To the extent that these indicators reflect differences in overall data validity and not changes in use of medical services, there appears to have been a steady improvement in the quality of incidence data collected nationally. While it is encouraging that recent data seem more accurate than those collected previously, one must be impressed by the difficulty of making comparisons among incidence rates from four programs whose data differ so widely in quality.

USES OF INCIDENCE DATA

How may one use and interpret the information that has been collected on U.S. cancer incidence? A frequent use is to indicate the overall size of the cancer problem in the United States. The American Cancer Society for a number of years has published these figures based on the New York and Connecticut Tumor Registries, the TNCS, and the SEER Program (*61*). These numbers serve to educate the public, to aid those who determine government policy, and, in conjunction with mortality data, to assess the burden of cancer on various segments of the U.S. population.

A criticism of the use of NCI data for this purpose has been that the data were inaccurate because they came from a population not representative of the entire U.S. population (*3*). The population covered by the SEER Program is, in fact, on the average somewhat younger and better educated and has a higher mean family income than the total U.S. population. In addition, persons living on farms and rural blacks are underrepresented and urban blacks are overrepresented. Despite these differences, the cancer mortality experience of the SEER Program-covered population is quite similar to that of the total U.S. population (*4*). Moreover, the issue of whether the SEER Program-covered population is representative of the entire U.S. population is of relatively little scientific importance. A population not entirely representative can still produce reasonably accurate and reliable estimates of incidence if one knows the nature and extent to which the population differs from the total U.S. population and if one uses appropriate methods of statistical adjustment. There also is no apparent need for great accuracy of these cancer morbidity figures. National estimates of cancer incidence that are slightly off the mark neither greatly misinform the public nor distort the ability of Congress to determine how much money it wishes to allocate for cancer research.

Another use of national cancer incidence data is to identify demographic groups who have exceptionally high or low risk of cancer. Such information helps physicians advise persons of their risk of cancer and helps target programs for early detection and prevention. The observation that malignant melanoma incidence was high among whites in New Mexico, for example, led to efforts to educate physicians and the public about melanoma recognition and treatment (*62*). Knowledge about high- and low-risk groups may also lead to etiologic hypotheses that can be tested through specific epidemiologic studies. For these purposes, data generally are more valuable if they come from clearly defined demographic groups in restricted geographic areas rather than from a cross section of the U.S. population. Under the first approach, subjects are identified who can later be traced and enrolled in detailed etiologic or follow-up studies. The information collected under the second approach comes from individuals who may be scattered throughout the country and cannot feasibly be enrolled in such studies.

A further use of national cancer incidence rates is to identify time trends in the occurrences of specific tumors. The SEER Program was initially envisioned as a cancer surveillance system (*4*), capable of detecting increases in the incidence of common cancers and the appearance of unusual new cancer types, such as angiosarcoma of the liver that occurs in workers exposed to vinyl chloride (*63*). In theory, incidence is preferable to mortality for surveillance data because case-fatality rates change over time and because increased incidence may not be rapidly reflected by increased mortality for those cancers that are not quickly fatal. The superiority of incidence data is unproved, however, and some authors believe that mortality data are more reliable indicators of cancer trends (*3, 4*). Perhaps the experience of the SEER Program over the coming years will provide evidence for or against the value of national cancer incidence surveillance.

Members of the public look at cancer incidence surveillance as a way to detect geographic "hot spots," i.e., places with exceptionally high rates. Often their concern is with environmental pollution from chemical wastes concentrated in a small space, such as occurred at Love Canal, N.Y. (*64*). This type of geographic surveillance poses some practical difficulties. First, if one surveys many geographic areas and many specific cancer types, some areas will be noted to have statistically significant high incidence rates due purely to chance and to the multitude of place-cancer combinations examined. Second, the population in an area may not be large enough to reveal, with statistical significance, a substantial increase in cancer incidence because most cancers occur relatively rarely and most environmental carcinogens appear to cause an increase in only one or a few cancer types. For example, 23 years of data were available from the roughly 4,900 residents of the Love Canal area, but these numbers would not have been sufficient to detect a 50% increase in the incidence of most cancers had such occurred (*64*). Third, not all inhabitants of an area are actually exposed to the environmental contaminant of interest (because they are recent immigrants or because the contaminant is not distributed throughout the area). The presence of these persons dilutes the measured effect of the contaminant and lessens the likelihood of detecting an increase in incidence. Lastly, identification of a "hot" area does not ensure that a previously unsuspected etiologic factor will be found responsible for the increased incidence. Sometimes the increase is largely due to factors already known to cause cancer, such as asbestos exposure in the shipbuilding industry (*65*), and often, despite myriad suspicions, no satisfactory explanation can be established. These practical difficulties and the potential to generate unfounded fears (or inappropriate reassurances) may explain why many epidemiologists lack enthusiasm for this type of small-area geographic surveillance.

PROBLEMS IN THE INTERPRETATION OF CANCER INCIDENCE DATA

Interpretation of cancer incidence estimates poses several problems for the users of these data. First, cancer incidence rates may not accurately reflect a population's exposure to the causes of cancer because the rates are measures of clinically detected disease only. Cancer incidence is a function of three separate rates: *a*) the rate of cancer initiation (due to the accumulated factors that cause cancer), *b*) the rate which persons transit from initiation to recognition of the cancer (due to biologic factors promoting tumor growth and sociologic factors influencing tumor detection), and *c*) the rate at which persons with occult cancer are removed from the population by death. An increase over time in the incidence rate of cancer may thus be due to many factors, of which increased carcinogenesis is only one. An increased rate of cancer detection, a reduction in the relative rate at which people with cancer leave the population (due to migration or death from other causes), or a reduction in factors that retard cancer growth will also cause the measured incidence rate to rise. The first possibility requires careful consideration. An abrupt rise (≈15%) in breast cancer incidence was reported in 1974 following publicity given this disease after its diagnosis in Mrs. Ford and Mrs. Rockefeller (*58*). Part of the increased incidence was likely due to increased detection by women practicing self-examination and by physicians performing more screening examinations. Changes in diagnostic criteria (vide infra) may also have occurred. Whatever the explanation, by 1976 the rates had returned nearly to 1973 levels (*58*). Since the early 1970's the NCI Cancer Control Program, the American Cancer Society, and state and local health agencies have mounted large-scale projects to promote screening and early self-recognition of cancer. Many of these efforts have been directed at the populations covered by the SEER Program and have probably inflated the SEER Program-measured cancer incidence rates apart from any real increase in cancer onset.

Current and past U.S. cancer incidence data are based principally on the diagnoses recorded by physicians in the hospital record. This information is not standardized and will vary according to physician preferences for particular diagnoses. The basis for the determination of what actually is cancer has changed with time, especially for lesions of "borderline" invasiveness. For example, papillary tumors of the urinary bladder that were once classified as benign transitional cell papilloma are now usually diagnosed as grade I transitional cell carcinoma. More subtle shifts in diagnostic criteria may have occurred for cancers of other sites such as the endometrium, prostate gland, and breast. Changes such as these may underlie observed temporal or geographic differences in incidence.

Another difficulty with interpreatation of incidence rates is the variable levels of completeness of data from different sources. Despite intense efforts to find all new cases of cancers, some cancer patients are always missed due to migration from the coverage area to an uncovered hospital or because of oversights by data collection staff. The completeness of case identification appears to vary considerably for data collected at different times or at different places, which may account totally or partly for reported differences in incidence rates. Thus in comparing two incidence rates, one needs to know the level of completeness of the two data sets, but such figures are hard to come by. Although the DCO figure provides a crude basis for comparing completeness, it is an imperfect measure. As noted above, the DCO figure is affected by the accessibility of medical care, and differences in medical care use may confound inferences based on the DCO figure.

The data in cancer surveys and tumor registries are often based on limited diagnostic information. Among all lung cancer cases included in the TNCS, for example, 40% lacked a specific histologic diagnosis and 16% had not been confirmed as cancer by microscopic examination (*32*). For cancers of less accessible sites such as the pancreas, stomach, and brain, specific diagnoses are frequently not available in the patients' records. One therefore should not try to extract detailed diagnostic information from cancer incidence rates and may have to use data grouped by major anatomic site and with numerous diagnoses of unspecified histology.

Comparability of two sets of incidence data may also be compromised by variable inaccuracies in the census population estimates used to calculate incidence rates. Inaccuracies in census counts have ranged from 2½% to nearly 10% for age, race, and sex subgroups of the U.S. population, and greater degrees of inaccuracies may pertain for geographic subgroups of the U.S. population (*66*). Incidence rates for intercensal years require estimations of population that may be more imprecise. Thus the user of cancer incidence rates should bear in mind that small variations between two incidence rates may be due to differential inaccuracies in the population denominators and not to true differences in the occurrence rate of cancer. This caveat, of course, also pertains to analyses of mortality rates.

So that comparisons can be made, most U.S. cancer incidence rates are published as summary estimates that are "age standardized." This procedure reduces the effects of differing age structures in the population rates compared, but it does not eliminate them. In fact, the choice of a standard population can affect the results of comparison (*60*), and age-standardized rates that use recent U.S. census figures as a standard are heavily weighted by data from the very elderly. This group is less likely to be diagnosed accurately and has greatly increased its use of medical care over the past two decades. Preferred alternatives are to examine age- and sex-specific data or to use a truncated summary measure based on data from those under age 65.

CONCLUSIONS

Investigators have generated a vast amount of information on cancer incidence in the United States. Available data span almost 45 years and cover many different geographic populations in the United States. The groups included have been and continue to be predominantly urban, but most of the larger demographic segments of the population are now representd to some extent.

The existing data may prove useful to physicians in advising patients about cancer risk and in targeting prevention efforts. The data contribute to estimates of overall cancer morbidity, figures useful for public planning. Examination of cancer incidence rates for different populations can also lead to hypotheses about cancer cause.

Because cancer incidence rates have been generated with the use of differing methods of case ascertainment and because detection of cancer varies by year and region, rates must be compared cautiously. Comparisons of data may be affected by variable inaccuracies in census data, by the partial lack of standardization of pathologic diagnoses, and by distortions introduced by "age standardization." Despite these limitations, cancer incidence data, when paired with mortality data, provide a resource of readily available information on cancer occurrence in the United States.

Degrees of Malignancy in Human Primary Central Nervous System Tumors: Ornithine Decarboxylase Levels as Better Indicators Than Adenosylmethionine Decarboxylase Levels [1,2,3,4]

Giuseppe Scalabrino,[5] Daniela Modena,[5] Maria Elena Ferioli,[5] Mirella Puerari,[5] *and* Giovanni Luccarelli[6,7]

ABSTRACT—The levels of activity of ornithine decarboxylase (ODC) and adenosylmethionine decarboxylase (AMD) were measured in various types of primary human tumors of the central nervous system (CNS) and whenever possible were related to the malignancy of the tumor graded according to histopathologic criteria. In astrocytomas ODC levels increased linearly and progressively from infratentorial pilocytic astrocytoma (grade I) to glioblastoma multiforme (grade IV) and correlated well with the degree of histologic malignancy of the tumor. AMD activity levels, however, correlated with tumor malignancy only up to grade III astrocytoma. Medulloblastomas exhibited an unusual dichotomy with regard to the levels of polyamine biosynthetic decarboxylases (PBD): Medulloblastomas had the highest ODC activities of all the CNS tumors tested but had low AMD activities. In tumors of neuroepithelial tissue ODC level increases and, when present, AMD level increases were not due to proliferation of new blood vessels, because CNS hemangioblastomas had very low levels of both PBD activities. No significant differences in either of the PBD levels were observed among the several variants of meningiomas tested, the meningotheliomatous, the transitional, and the fibrous meningiomas. However, atypical forms of meningioma, i.e., those with mitotic figures, whatever the histologic variants, had higher levels of ODC, but not of AMD, than the typical forms, i.e., those without mitotic figures.—JNCI 1982; 68:751–754.

There is mounting interest in a variety of biochemical and/or immunologic molecules as potential markers for human CNS tumors. These molecules can be detected in neoplastic cells from which they may leak out into the CSF and be detected there (*1–3*). Polyamines for example are considered despite some limitations as helpful markers in the diagnosis of human brain tumors and in the evaluation of the degree of tumor malignancy and of effectiveness of therapy (*1, 4–6*).

High levels of putrescine and spermidine have been found in the CSF of patients with different kinds of untreated malignant brain tumors, whereas the polyamine contents in the CSF of cancer patients after clinical improvement declined nearly to the levels seen in reference patients with various nonneoplastic neurologic diseases (*7*). Further studies of Marton and co-workers (*8, 9*) emphasized that the elevations of putrescine and spermidine levels in CSF of patients with medulloblastoma correlated well with the progression of this tumor, whereas such a correlation was not always found in CSF of patients with glioblastoma multiforme or with anaplastic astrocytoma (*10*). Marton and co-workers (*11*) proposed a tentative explanation for the difference between the two types of tumor patients, those with medulloblastomas and those with supratentorial malignant gliomas.

The limited data available thus far on the polyamine contents of human brain neoplastic tissues agree in indicating that these tumors are generally characterized by putrescine concentrations higher than those of the normal human brain (*12, 13*). Furthermore, the extent of this putrescine elevation was found to be a reliable indicator of the degree of malignancy of brain neoplasms, according to conventional histopathologic criteria (*13*).

A previous study in our laboratory (*14*) demonstrated that the extent of the increases in the activities of ODC (EC 4.1.1.17) and AMD (EC 4.1.1.50) in the epidermis of human epitheliomas was directly proportional to the neoplasm's growth rate and therefore correlated well with the tumor's malignancy. To establish whether such a correlation exists between increases in these enzyme levels and the degree of growth rate and malignancy of the neoplasm in human organ tumors other than those of the skin, we determined the PBD levels in various types of human primary CNS tumors. Whenever possible, we studied tumors with well-defined grades of growth rate and malignancy according to conventional histopathologic criteria.

MATERIALS AND METHODS

Patients.—None of the cancer patients from whom the neoplastic tissues were obtained had received any antineoplastic therapy before neurosurgery nor did they have any other diseases. The mean ages for each patient group were: infratentorial pilocytic astrocytomas (grade I), 23 years; supratentorial astrocytomas (grade II), 26 years; supratentorial astrocytomas (grade III), 39 years; glioblastomas multiforme (grade IV), 57 years; medulloblastomas, 10 years; transitional meningiomas, 54 years; meningotheliomatous meningiomas, 53 years; fibrous meningiomas, 56 years; and hemangioblastomas, 56 years. Although we also measured

the levels of PBD activities in samples of human brain tissue taken from patient with nonneoplastic neurologic diseases (results not reported here), we do not believe it is correct to consider these values as normal control values. For obvious ethical reasons it is impossible to obtain fresh samples of normal human brain, i.e., tissues that are not autopsy specimens.

Human primary CNS tumors.—The neoplasms employed in this study were localized in different areas of the human CNS and were obtained by neurosurgical procedures from patients under general anesthesia. None of the neoplasms had any macroscopic necrotic areas or ulcerations. The excised neoplastic tissues were immediately cut into two pieces. The first and larger piece was quickly frozen in liquid nitrogen and used immediately for the enzyme assays. The second and smaller piece was fixed in Formalin, embedded in paraffin, and processed for the usual histologic examination to ascertain the type of neoplasm and the degree of its malignancy. The 5-µm sections cut from every specimen were stained routinely with hematoxylin and eosin and with Masson's trichrome stain. Glioma tumor specimens were routinely stained with Mallory's phosphotungstic acid-hematoxylin and with Cajal-Holzer stain. Sections from medulloblastomas were stained by the Bielschowsky method for reticulum impregnation. Histopathologic diagnosis for each neoplastic specimen was made without any information on the results of the enzyme assays. The histopathologic diagnosis and the grading of the neoplasms were made according to the principles of the WHO classification recently summarized by Zülch (*15*). For the astrocytomas and the meningiomas only, we followed an additional criterion of classification proposed by Rubinstein (*16, 17*). Neoplastic tissue samples that showed marked histopathologic heterogeneity, marked edema, or reactive changes were excluded. Metastases to the brain from extraneural neoplasms were deliberately excluded from our research, because they do not reflect the neoplastic transformation of any CNS structure and because they are frequently made up of mixtures of normal cells and neoplastic cells.

Chemicals.—L-[1-^{14}C]ornithine (60 mCi/mmol) and *S*-adenosyl-L-[carboxyl-^{14}C]methionine (60 mCi/mmol) were purchased from the Radiochemical Centre, Amersham, Buckinghamshire, England. All other chemicals were of the highest grade of purity available commercially.

Enzyme assays.—The activity of ODC was assayed as previously described (*14*), with the only difference being that the labeled L-ornithine in each incubation mixture was 0.2 µCi. Putrescine-activated AMD activity was assayed as described by Jänne and Williams-Ashman (*18*). Assays were always done in duplicate. The incubation was done as previously described (*14*). Samples were counted in a Tri-Carb liquid scintillation spectrometer (model 3365; Packard Instrument Co., La Grange, Ill.). Counting efficiency was determined by both internal and external standardizations and was 80±5% by both methods. The amount of $^{14}CO_2$ liberated from tubes containing heat-inactivated enzyme or water was subtracted from all other samples before the correction for protein content. When the lowest activities were measured, the cpm values were as follows: 200 cpm with a blank value of 60 cpm for ODC and 350 cpm with a blank value of 40 cpm for AMD. Protein content was determined by the method of Geiger and Bessman (*19*), with bovine serum albumin as standard. The protein content of each assay tube ranged from 2 to 3 mg in the ODC assay and from 1 to 1.5 mg in the AMD assay.

Differences in enzyme activity levels were analyzed by Student's *t*-test.

RESULTS

Table 1 presents the levels of ODC and AMD activities observed in some types of human brain neuroepithelial tumors. The level of ODC activity in the astrocytoma group progressively and significantly increased from infratentorial pilocytic astrocytoma to supratentorial glioblastoma multiforme through supratentorial astrocytomas of grades II and III. The increase appeared to be directly proportional to the degree of neoplastic dedifferentiation, as indicated by the histopathologic criteria for the malignancy for these types of tumors. Furthermore, if one adopts Rubinstein's suggestion (*16*), dividing the astrocytomas regardless of their localization into 2 groups, the first of which includes the benign and differentiated forms (grades I and II astrocytomas) and the second of which includes the malignant and dedifferentiated forms (grade III astrocytoma and glioblastoma multiforme), one can observe that the value of ODC activity for dedifferentiated astrocytomas was nearly six times that of differentiated astrocytomas. It can also be seen that medulloblastoma, a brain tumor highly malignant in its clinical course, had the highest level of ODC activity among all the human CNS tumors of any histogenetic origin tested by us.

When we consider the activity levels of the other PBD AMD in the same types of brain tumors, we can see that this enzymatic activity progressively and significantly increased from the infratentorial pilocytic grade I astrocytoma to the supratentorial grade III astrocytoma, so that it, as well as ODC, followed quite well the degree of histopathologic malignancy of the tumor. However, it can also be seen that there was no further increase in AMD activity between supratentorial grade III astrocytoma and glioblastoma multiforme. Therefore, the increase in AMD activity from infratentorial pilocytic astrocytoma (grade I) to glioblastoma multiforme (grade IV) was not complete similar to that in ODC activity. The AMD activity level in the dedifferentiated astrocytomas, as compared with that in the differentiated astrocytomas, was about twofold and consequently its increase was of a lesser magnitude than that of the ODC activity (table 1).

The surprising finding is, however, that medulloblastomas showed a clear dichotomy between the levels of the two PBD activities, revealing the highest ODC level and the lowest AMD level in any of the human brain tumors of neuroepithelial tissue we tested (table 1). It seems noteworthy that the AMD activity level of the medulloblastomas (all of which originated in the cerebellum) was very close to that of the infratentorial pilocytic astrocytomas (all of which were also localized in the cerebellum), despite the great difference between the degrees of malignancy of these two types of tumors.

TABLE 1.—*Activities of ODC and AMD in different primary human neuroepithelial tumors*

Inasmuch as the vascular component usually represents a very large part of the tumor bulk in human CNS tumors, particularly in astrocytomas and medulloblastomas (*20, 21*), we measured the levels of PBD activities in hemangioblastomas, human brain tumors of vascular origin. We wished to ascertain whether the enhancements in PBD activities that we saw in astrocytomas and medulloblastomas might be at least in part related to increased formation of new blood vessels in the neoplastic tissues. This we found was not to be the case, and the data in table 2 show that hemangioblastomas of the human CNS had very low levels of PBD activities.

TABLE 2.—*Activities of ODC and AMD in various human brain blood vessel and meningeal tissue tumors*

Code	Tumor type	No. of patients	Enzyme activities, pmol $^{14}CO_2$/mg protein/30 min[a]	
			ODC	AMD
A	Hemangioblastoma	4	0.8±0.12	3.3±0.87
B	Meningeal tumors:			
	Fibrous meningioma	6	6.0±1.33	60.4±8.52

	Transitional meningioma	8	5.6±1.19	45.8±6.16
C	Typical meningiomas	20	6.2±1.05	51.8±5.22
D	Atypical meningiomas	10	11.6±1.68	61.7±6.81

Statistical comparison[b]

Code	ODC *P*-value[c]	AMD *P*-value[c]
C vs. D	<0.05	NS

[a] Results are means ± SE.
[b] Evaluated by Student's *t*-test. NS=not significant.
[c] No other statistically significant differences were found within the meningioma group.

Table 2 shows that the levels of ODC and AMD activities were not significantly different in the three types of human meningiomas, the transitional, the meningotheliomatous, and the fibrous meningioma. Nevertheless, if we accept the suggestion of Rubinstein (*17*) to divide the meningiomas into atypical and typical forms on the basis of the presence or absence of mitotic figures regardless of histologic variants, we observe that ODC levels in the atypical forms were nearly double those of the typical forms, without significant corresponding differences between the AMD levels.

DISCUSSION

The present study stresses that in different types of human brain neoplasms the extent of ODC enhancement and in some types also the extent of AMD enhancement are correlated with the growth rate and the degree of dedifferentiation of the tumor as determined by histopathologic criteria. The progressive increase in ODC activity is particularly striking in the different grades of astrocytomas and in glioblastoma multiforme, whereas the progressive increase in AMD activity is clearly demonstrated only from astrocytoma grades I to III. It is well known that the neoplastic growth rate is much slower in low-grade, well-differentiated astrocytomas than in the high-grade, malignant gliomas, including glioblastoma multiforme (*22*). Within the astrocytoma group, the size of the ODC increase is also directly proportional to the number of cells engaged in DNA synthesis, which has been demonstrated to be greater in high-grade astrocytomas and in glioblastoma multiforme than in low-grade astrocytomas (*23*). Like the activity of ODC, the activities of other enzymes, such as hexokinase, glucose-6-phosphate dehydrogenase, and phosphogluconate dehydrogenase, have been demonstrated to increase linearly in proportion to the degree of neoplastic dedifferentiation in astrocytomas of grades I to IV, which includes glioblastoma multiforme (*24*).

Our measurements of the levels of ODC activity in astrocytomas and in glioblastoma multiforme indirectly agree with and complement the results provided by Harik and Sutton (*13*), who reported that putrescine content is higher in high-grade astrocytomas than in low-grade astrocytomas. It is well known that only ODC makes putrescine in eukaryotic cells (*25*). Our results showing that infratentorial astrocytomas have much lower ODC levels than supratentorial astrocytomas are once again in agreement with those of Harik and Sutton (*13*), who demonstrated that infratentorial astrocytomas have lower putrescine levels than the supratentorial ones.

Furthermore, our results supplement those of Harik and Sutton (*13*), since we determined the levels of PBD activities in medulloblastomas, which was not included in their study. Medulloblastomas show a very peculiar dichotomy between these two enzyme levels, with striking ODC enhancement not accompanied by a similar change in AMD activity. At present, it is exceedingly difficult to account for this phenomenon. This finding seems to us to be of great interest and quite new in human oncology, since to the best of our knowledge it is the first report of a human tumor with a very high ODC level in combination with a low AMD level. A similar dichotomy has already been reported for rat hepatomas with different growth rates (*26*) and for mouse skin tumors (*27*).

Again, our results also extend those of Harik and Sutton (*13*) for meningiomas, since we have differentiated some histologic types of these tumors, albeit without observing any significant difference in the levels of either ODC or AMD activities among the morphologic variants. However, the incidence of mitotic figures in tumors of meningeal tissues has been claimed by Crompton and Gautier-Smith (*28*) to be an important criterion in the assessment of the likelihood of recurrence and a rough indicator for rapid growth. Similarly, we can state that in meningiomas the ODC but not the AMD level increase is related to the neoplastic growth rate, since we demonstrated that the atypical forms have higher levels only of ODC than the typical forms.

Although it is always difficult to draw conclusions in oncology from merely quantitative studies, the results of the present study, together with those of a previous study (*14*) on the levels of PBD activities in different human tumors of the brain and the skin, indicate that assays of these enzyme levels in tissue specimens obtained after the surgical removal of the neoplasms may frequently be a useful tool for the evaluation of the grade of growth rate and malignancy of human neoplasms.

An Increased Risk for Lung Cancer Mortality Associated With Sugarcane Farming[1,2,3]

Henry Rothschild[4] *and* James J. Mulvey[4,5]

ABSTRACT—In a study to determine putative occupation-related factors responsible for the excessive mortality due to lung cancer in southern Louisiana, the next-of-kin were interviewed of 284 of 400 persons (71%) randomly sampled from a total of 815 persons who died of lung cancer during 1971 through 1977 and had lived in any of 10 parishes (counties) of southern Louisiana. Of the decedents, 108 (38%) had been employed for at least 6 months as sugarcane farm workers at some time during their lives. Logistic regression analysis indicated this industrial involvement differed significantly ($P<0.0001$) from that of a control group, consisting of persons who had died of any cause other than lung cancer and who were matched for year of death, age, sex, race, and parish of residence; only 58 (20%) matched controls had had sugarcane farm employment (odds ratio=2.4; 95% confidence interval, 2.0–2.9). Employment in other industries or tobacco consumption could not account for the elevated risk of lung cancer mortality associated with sugarcane farming. After adjustment for smoking, the relative risk estimate of lung cancer mortality for sugarcane farm workers was 2.4 (95% confidence limits, 1.7–3.6). The sugarcane farmers who died with lung cancer had worked for longer periods in the sugarcane farm industry than did those sugarcane farmers in whom lung cancer did not develop ($P=0.006$). No specific histopathologic cell type was noted to be increased in persons who had been employed in sugarcane farming; however, 2 sugarcane farmers had had mesotheliomas.—JNCI 1982; 68:755–760.

As has long been recognized, persons in certain occupations have an increased risk for lung cancer compared with the risk of the general population (*1–9*). One of the many industries suggested to be associated with increased risk for lung cancer, for example, is shipbuilding (*8, 9*), which has been a predominant industry in Louisiana for several decades (*10*). In the course of a study on the familial aggregation of lung cancer, we noted that an unusually large number of persons who died with lung cancer had been sugarcane farmers (*11*). Coincidently, the parishes involved in sugarcane production were located in southern Louisiana, an area with excessive mortality due to lung cancer (*12*). To further investigate the validity of this observation, we conducted a matched-pair case-control study of lung cancer mortality in 10 parishes of southern Louisiana.

MATERIALS AND METHODS

A computerized listing of deaths in the 10 rural, southern Louisiana parishes (East Feliciana, Iberia, Lafourche, Pointe Coupee, St. Bernard, St. Helena, St. James, St. John, St. Martin, and West Feliciana) used in our previous studies (*12, 13*) was provided by the Office of Public Health Statistics, Louisiana Health and Human Resources Administration. Four parishes (Lafourche, Iberia, St. Bernard, and St. Martin) ranked in the highest 3% for all counties of the United States for lung cancer mortality among white men during 1950–69 (*14*).

To augment the limited data on the death certificates, we randomly selected 400 of the 815 persons who died in the 10 target parishes during 1971 through 1977 and had lung cancer listed as the cause of death (ICD codes 162 through 163) (*15*). The cause of death was verified for this sample by medical or pathologic records. A computer program matched each of these decedents for sex, race, age at death within 10 years, year of death, and parish of usual residence with a person who died of any cause other than lung cancer. In the case of multiple matches, the control whose age was closest to the case's age was selected. The controls included 13 persons whose deaths were attributed to other neoplasms.

We were able to interview the nearest living relative of 284 matched case and control pairs; 78% were spouses and 22% were first-degree relatives. The interviews were done by persons trained in interviewing techniques and with the knowledge of each person's case or control status. By means of a structured questionnaire, detailed employment histories, including specific information about the duties performed and materials handled for all jobs held 6 months or longer, were obtained. These jobs were classified according to the SICM (*16*). Closed-format questions inquiring whether the decedent had ever been employed in the sugarcane and/or shipbuilding industries were included. The occupational section of each questionnaire was concluded by a review with each respondent of a checklist of industries of "usual" employment. The smoking information obtained for each decedent included: whether a nonsmoker, smoker, or ex-smoker; cigarette, cigar, or pipe smoker; the average amount smoked per day; the total number of years smoked; and the years smoking started and/or stopped.

Estimates of the RR (odds ratios) of employment on lung cancer were calculated for each of 15 industrial categories and for various parameters: age of death (≤63, >63 yr), race (white, black), sex (male, female), and smoking status (ever smoker, never smoker) (*17*). Using logistic regression, we tested for interactions of the RR for employment in sugarcane farm or shipbuilding industries with the various parameters (*18*). The covariates and risk indicators were regressed

upon the outcome variable (disease status) with the use of both a retrospective and prospective representation of these data (*19*) Dummy variables were used in the completed program to calculate the logistic coefficients.

Sequential deletions of terms were made to obtain a final well-fitting model. The decision to delete parameters was based on the *t*-tests for significance of each parameter estimate, on the changes in the value of the log likelihood, and on the goodness of fit of the models compared with the observed stratified odds ratios. The log linear model was used to test for specific three-way interactions (*20*). When effect modification was absent, summary RR point and interval estimates were calculated by the Mantel-Haenszel method (*21*).

Methods for histopathologic slide ascertainment and classification have been described previously (*13*). All available original histopathologic slides of the cases were reviewed separately by two pathologists who later conferred without knowledge of prior diagnosis to decide on the final histopathologic classification. Multiple sections of tissue were usually available. The World Health Organization classification of lung cancer (*22*) was used to categorize the tumors, with one modification; i.e., the group of small cell anaplastic carcinomas was not further divided into subcategories.

RESULTS

Table 1 shows the estimated RR for the usual industrial classifications and selected subdivisions for the 284 persons who had died of lung cancer and their controls. Shipbuilding, the usual industry of 13 cases and 9 controls, was the industry of employment for 6 months or more of 48 cases and 40 controls (odd ratio=1.2). Using the logistic method revealed an interaction term between shipbuilding as the usual industry of employment and sex, males having an odds ratio of 1.7 and females having one of 0.3. However, the small sample size for this group precluded any further analysis.

TABLE 1.—*Estimated RR for the usual industry of employment*[a]

Industry (SICM classification)	Cases	Controls	Odds ratio (95% confidence interval)[b]
Agriculture (0100–0132, 0134–0783)	25	24	1.1 (0.6, 1.9)

[a] For ≥6 mo.

[b] Includes both cases and controls.

[c] Farmers who grew a variety of crops including sugarcane were included in this category.

Sugarcane farming was the usual industry of 45 (16%) cases and 24 (8%) controls (odds ratio=2.3; 95% confidence interval, 1.8–3.0). Furthermore, 108 (38%) lung cancer cases and 58 controls (20%) (odds ratio=2.4; 95% confidence interval, 2.0–2.9) had "ever" (≥6 mo) been employed in this industry; many persons had worked for several months during the harvest and planting seasons each year.

Because the major findings of this study pertained to sugarcane farm employment, subsequent analysis focused on estimation of the RR of lung cancer mortality for cases having ever had a sugarcane farm occupation. Logistic analysis indicated that employment in shipbuilding for 6 months or more was not confounding the observed association between sugarcane farming and increased lung cancer mortality. Four cases and 1 control had shipbuilding as their usual occupation and sugarcane farming as a secondary occupation (table 2). Most (59%) who worked as sugarcane farmers for 6 months or more were categorized as having "farming" as their usual employment. Using the logistic method, we found that employment in other industries did not confound the association between increased lung cancer mortality and sugarcane farming.

Although based on relatively small numbers, the increased risk for lung cancer mortality of sugarcane farmers could not be accounted for by cigarette smoking (table 3). No significant heterogeneity was found between the odds ratios of smokers and nonsmokers with the use of a log linear model to detect a three-way interaction term (likelihood

TABLE 3.—*RR for ever employed in sugarcane farming according to smoking category*

Smoking category (No.)	Case or control	Employment in sugarcane farming[a]			Odds ratio (95% confidence interval)[b]
		Yes	No	Total	
Nonsmoker (75)	Cases	3	10	13	0.9 (0.2, 3.9)
	Controls	15	47	62	
	Total	18	57		
Smoker[c] (493)	Cases	105	166	271	2.6 (1.8, 4.0)
	Controls	43	179	222	
	Total	148	345		

[a] For ≥6 mo.
[b] Test-based 95% confidence interval (23).
[c] Includes cigarette, cigar, and pipe smokers.

ratio chi square, 1.85; P=0.17). Decedents for whom cigarette pack-year data were available were classified as "moderate" smokers (≤40 pack-yr) and "heavy" smokers (>40 pack-yr). No significant heterogeneity in the RR for lung cancer was found for moderate smoking sugarcane farmers (odds ratio=1.7) and heavy smoking sugarcane farmers (odds ratio=2.7). The summary RR for sugarcane farmers adjusted for smoking was 2.4 (95% confidence interval, 1.7–3.6). Matching in the analysis was not retained because of the dearth of nonsmoking discordant pairs for persons employed in sugarcane farming.

The odds ratios for sugarcane farmers were increased irrespective of race, sex, or age (table 4). Smoking was not a confounding variable because the smoking-adjusted odds ratios for these indicators did not differ significantly from the crude odds ratios. Calculation of a summary RR estimate was indicated by the lack of heterogeneity between the odds ratios of the categorical variables. When smoking, age, race, sex, and usual industry were simultaneously taken into account in the logistic model, the adjusted summary RR estimate for lung cancer mortality was 2.8.

TABLE 4.—*Estimated RR for sugarcane farming according to race, sex, and age category adjusted for smoking*

Variable (No.)	Case or control	Employment in sugarcane farming[a]		Odds ratio (95% confidence interval)[b]	Smoking-adjusted odds ratio (95% confidence interval)[c]
		Yes	No		
Race					
White (480)	Case	78	162	2.6 (1.7, 3.9)	2.8 (1.7, 4.4)
	Control	38	202		
Nonwhite (88)	Case	30	14	2.6 (1.1, 6.1)	2.3 (0.9, 5.7)
	Control	20	24

TABLE 5.—*Logistic regression fit for lung cancer mortality data*

Covariate	Logistic coefficient[a]	Standard error	Coefficient:standard error	P-value
Smoking	1.005	0.170	5.907	0.00001
Sugarcane	0.458	0.101	4.554	0.00001
Shipbuilding–sex	0.357	0.130	2.746	0.007

[a] The odds ratio = exp (2×logistic coefficient).

The persons who died of lung cancer were employed longer in the sugarcane industry (28.4 yr) than the controls who had worked in that industry (20.7 yr). A two-tailed t-test to compare cases and controls for differences in length of employment showed that the 95% confidence interval for this difference in mean number of years of sugarcane farm employment was 2.1–13.2 years.

The results of a retrospective approach of regression on sugarcane employment as the outcome variable were consistent with those of the prospective approach to modeling. The final well-fitting logistic regression model of the prospective representation of these data suggested that the odds in favor of lung cancer mortality were influenced by smoking, sugarcane farming, and a shipbuilding–sex interaction (table 5). The goodness-of-fit chi-square P-value for this model was 0.77.

A review of specific histologic types of lung cancers revealed no predominant cell type associated with sugarcane farm employment. Of the 284 decedents with lung cancer, pathologic material was obtained for 205 cases (72%) (table 6). Squamous cell carcinoma and small cell anaplastic carcinoma were the most common tumor types, closely followed in frequency by adenocarcinoma. Analysis of these data indicated that the distribution of histopathologic types was not significantly different for persons employed in sugarcane farming compared with those never employed in this industry.

TABLE 6.—*Histologic types of lung cancers in 205 cases*

Tumor type	Sugarcane farm employment,[a] No. (%)	No sugarcane farm employment, No. (%)
Squamous cell	26 (32.5)	39 (31.2)
Small cell anaplastic	17 (21.3)	26 (20.8)
Adenocarcinoma	15 (18.8)	23 (18.4)
Bronchiolo-alveolar	1 (1.3)	1 (0.8)

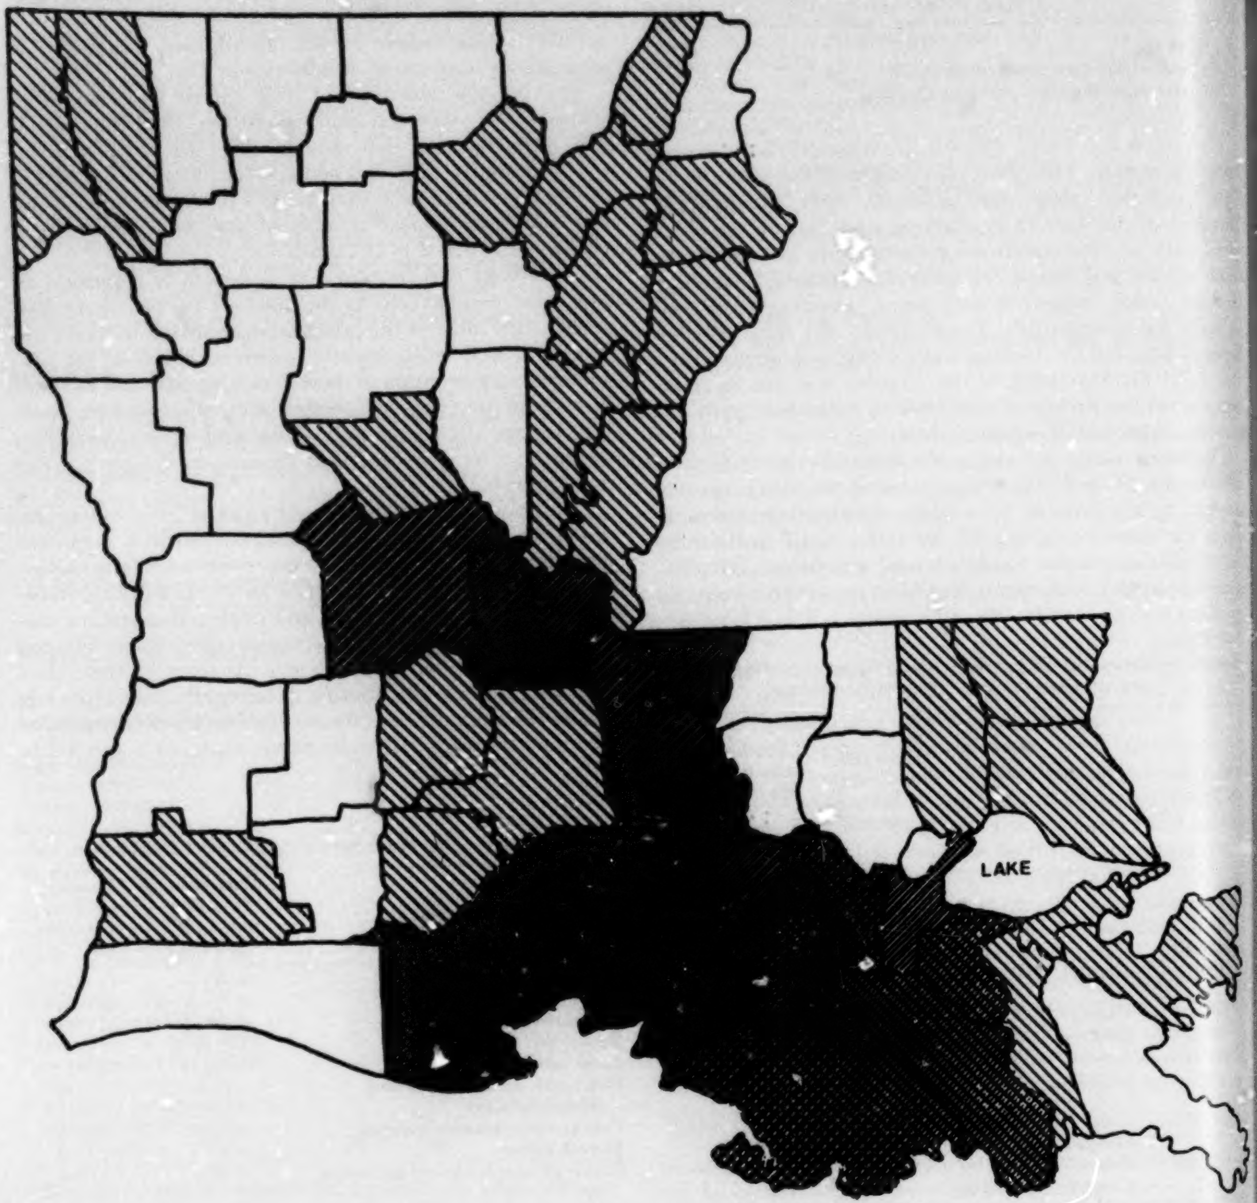
Total	80 (100.2)	125 (100)

[a] For ≥6 mo.

DISCUSSION

The relationship between sugarcane farming and lung cancer was not anticipated and is being reported because a positive association was observed. This is an instance for which the causal hypothesis was generated by the data rather than the investigator. Therefore, this positive association requires cautious interpretation until the work has been reproduced in another investigation.

No association between sugarcane farm industry employment and lung cancer mortality has been reported previously. Several reasons may contribute to the discrepancy between our findings and previous studies in Louisiana, which used death certificate listings only to obtain the usual occupation of decedents (*9, 25*). On many of the death certificate listings, a sugarcane farmer was reported as "farmer," with no indication of the type of crop he was engaged in producing. Also, women living on farms were often reported as "housewives" on the death certificates, but the interviews revealed that many of these women had



TEXT-FIGURE 1.—A map of the parishes (counties) of Louisiana showing those where sugarcane is produced and those in the top quarter for age-adjusted mortality due to lung cancer for white men (1967–76) (*12*). ▨, Parishes in the top quarter of lung cancer mortality. ■, Parishes growing sugarcane for sugar production.

worked in the fields planting and harvesting sugarcane.

We were unable to estimate the percentage of the work force of the target parishes or of Louisiana involved in sugarcane farming because accurate employment figures were not available for the years prior to 1970. Thus we are unable to calculate the incidence of lung cancer for persons working in this industry.

Many of the parishes in Louisiana that grow sugarcane have high mortality due to lung cancer (*12*) (text-fig. 1). In the continental United States, sugarcane production is a major industry in only two other states: Florida and Texas. Two of the three sugarcane-growing counties of Florida (Indian River and Palm Beach) but none of three counties in Texas have a high mortality due to lung cancer (*14*). In Texas, however, sugarcane farming was started only after 1970 (Jones JP: Personal communication). Thus sufficient time may not have elapsed for the disease to be manifested.

Several hypotheses may explain the association between increased lung cancer mortality and sugarcane farming. It may be related to the manner in which the sugarcane is harvested. When mechanized sugarcane harvesting equipment was introduced during the 1930's and 1940's, burning of the cane to remove excess leafage became common practice. Harvesting the cane is done in three steps: 1) The cane plant is cut down; 2) a short time later the cane rows are fired and the excess leafage is burned away, leaving the cane stalk; and 3) the stalks are transported to the sugarmills for processing into raw sugar. The burning of the cane rows greatly increases airborne suspended particles that may act as an irritant to the respiratory tract tissue. This irritation could promote increased susceptibility to other carcinogens. The burning process may also convert chemicals used in the production of sugarcane to substances with carcinogenic potential. Comparison of the lung cancer mortality for countries involved in sugarcane production or those that do or do not practice burning is difficult at this time because of the unreliable county-specific mortality statistics for many of these countries.

The association could be a noncausal relationship reflecting an association of both employment and mortality with some as yet unidentified factor. Many of the workers in sugarcane farm occupations are of low socioeconomic level, which may implicate such factors as nutrition, sanitation, housing, and access to health care (*26*). Perhaps not coincidently some of the herbicides, plant-growth regulators, and insecticides used in the Louisiana sugarcane industry contained arsenic or chlorinated hydrocarbons, chemicals that have been identified with increased risk of cancer in humans (*27*).

Although most of the persons in our study employed in sugarcane farm occupations were growers and field laborers, 34 of the field laborers had at some time worked as bagasse handlers (21 cases and 13 controls). Bagasse is the sugarcane plant residue left after the juice has been extracted. Bagassosis, a relatively benign occupational respiratory disease, has been described in persons exposed to moldy bagasse (*28*) and has been associated with inhalation of spores of *Thermoactinomyces vulgaris* (*29*). This exposure might suggest an association with a microbial contamination of the products of the sugarcane industry.

Although no consistent histopathologic tumor type was associated with sugarcane farm employment, in our study population we found 2 sugarcane farmers who had no discernible exposure to asbestos but had mesotheliomas. Mesothelioma, a rare tumor associated with asbestos exposure, was reported in 5 patients in India who were occupationally exposed to sugarcane rather than to asbestos (*30*).

Both the use of next-of-kin interviews with nonblinded interviewers to obtain information concerning diseased persons and the retrospective design of this study impose restrictions on the investigator's ability to make definitive statements regarding disease–smoking–occupation interactions. Therefore, the results of this study should be considered with respect to its design and the inherent biases. Although epidemiology is not a precise method, when applied properly, it can be a valuable tool to provide direction in our search for potential health hazards.

ABSTRACT—The IgG2a monoclonal antibody (MoAb) 376.96S, secreted by a hybridoma derived from a mouse immunized with cultured human melanoma cells COLO 38, reacts with a single 94,000-dalton glycoprotein that is peripherally associated with the plasma cell membrane of cultured melanoma cells. Indirect immunofluorescence analysis with cryostat thin sections of human tissues showed that this antigen is absent from a large variety of normal tissues but is readily detectable on melanomas, nevi, and several different carcinomas. The MoAb 376.96S binds with cultured melanoma and carcinoma cell lines to a similar extent and can mediate both complement-dependent and cell-dependent lysis of these cells. The 94,000-dalton glycoprotein detected by MoAb 376.96S is distinct in its tissue distribution, antigenicity, and molecular profile from several structures previously identified with monoclonal antibodies that have similar molecular weights. JNCI—1982; 68:761–769.

Melanoma represents one type of human tumor in which the hybridoma technique has been successfully used to develop MoAb to tumor-associated antigens (*1–9*). Several of the melanoma-associated antigens identified with MoAb have apparent MM in the range of 95,000. Woodbury et al. (*2*) and Dippold et al. (*4*) have defined single-chain membrane-bound antigens with the apparent MM of 97,000 and 95,000 daltons, respectively. Mitchell et al. (*6*) have described a 95,000-dalton melanoma-associated antigen which is associated with three additional components with MM of 11,600, 29,000, and 26,000 daltons respectively, and Wilson et al. (*9*) have identified a 94,000-dalton glycopolypeptide which is associated with 75,000-, 70,000-, and 25,000-dalton structures. In this study we describe a new 94,000-dalton glycoprotein that is expressed by melanoma and carcinoma cells and is distinct from similar MM glycoproteins identified with monoclonal antibodies in terms of tissue distribution, antigenicity, and molecular profile.

MATERIALS AND METHODS

Monoclonal antibodies.—The MoAb 376.96S and 345.134 are secreted by hybridomas constructed with the murine myeloma cell line Sp2/0-Ag14 and splenocytes from BALB/c mice immunized with cultured human melanoma cells COLO 38, according to the procedures we have described elsewhere (*5*). The MoAb 345.134 identifies a membrane-bound antigen which is expressed by human melanoma cells but is undetectable on melanocytes. This antigen, which is expressed on a large variety of normal and malignant cells, consists of an 85,000-dalton glycoprotein linked to a 30,000-dalton polypeptide by disulfide bonds. The serologic and immunochemical characterization of the MoAb 345.134 was described elsewhere (*10*). The MoAb 465.12S was prepared with the use of splenocytes from a mouse immunized with cultured human melanoma cells M21. The MoAb 465.12S reacts with a cytoplasmic antigen expressed in human melanoma cells, but is undetectable in melanocytes. This antigen, which is expressed in epithelial cells from several organs and in a variety of tumors, consists of four glycopolypeptides with MM of 94,000, 75,000, 70,000, and 25,000 daltons, respectively. The method of preparation as well as the serologic and immunochemical characterization of this antibody have been described elsewhere (*11*). The hybridomas secreting these monoclonal antibodies have been subcloned and have been propagated in vitro and in vivo for about 1 year. Immunodiffusion analysis with rabbit anti-mouse Ig antisera (Litton Bionetics Inc., Kensington, Md.) indicated that both antibodies were of the IgG2a subclass. The MoAb I_{12} to a 95,000-dalton membrane antigen (*4*) was provided by Dr. W. Dippold, Dr. K. Lloyd, and Dr. L. Old of the Sloan-Kettering Institute, New York, N.Y.

Conventional xenoantisera.—FITC-labeled rabbit anti-mouse IgG1 and IgG2a antisera were purchased from Meloy Laboratories Inc., (Springfield, Va.). Both reagents have a fluorescein-to-protein ratio of 3 and have been used at a protein concentration of 1.5 mg/ml. Before use, one volume of each antiserum was sequentially incubated at 4°C for 60 minutes with one volume of packed $ABRh^+$ erythrocytes and of packed cultured human melanoma cells M10 to absorb contaminating antibodies that may cause false-positive reactions. The adsorbed FITC-labeled reagents did not stain cultured cell lines or tissue substrates.

Cultured human cell lines.—Human cells in long-term culture were maintained in RPMI-1640 medium containing 10% calf serum. A confluent monolayer of melanoma cells (BwV)

ABBREVIATIONS USED: ADCC=antibody-dependent cell-mediated cytotoxicity; FITC=fluorescein isothiocyanate; IIF=indirect immunofluorescence; MoAb=monoclonal antibody (antibodies); MM=molecular mass(es); PBS=phosphate-buffered saline; SDS-PAGE=sodium dodecyl sulfate polyacrylamide gel electrophoresis; SpA=purified protein A from *Staphylococcus aureus.*

or a suspension of melanoma cells (COLO 38, M21) in a T-25 flask (Falcon Plastics, Cockeysville, Md.) were intrinsically radiolabeled with 2 mCi D-[6-^{3}H(N)]glucosamine hydrochloride, 30 mCi/mmol (New England Nuclear Corp., Boston, Mass.), according to the method described by Duksin and Bornstein (*12*) or they were surface labeled with ^{125}I by the Iodogen method of Salisbury and Graham (*13*). The cells were solubilized with Nonidet P40 detergent in PBS containing 10 μM of the proteolytic inhibitor phenylmethylsulfonyl fluoride. The resulting extract was cleared by centrifugation at 7,000×*g* and stored at −20°C. Cell extracts obtained with 3 *M* KCl or urea were dialyzed against PBS (pH 7.0) prior to use.

Tissue specimens.—Tissues were obtained surgically from untreated patients and from patients undergoing different therapeutic regimens. Normal tissues were obtained from sites directly adjacent to neoplastic lesions. Tissue specimens were snap-frozen in liquid nitrogen, and two consecutive cryostat sections of 4-µm thickness were obtained from each frozen tissue: One section was stained with toluidine blue (0.1% in PBS) and the other section was fixed for 10 minutes in cold absolute acetone and then used in the IIF test. Absolute acetone was chosen over other fixatives because it retained the most detail after fluorescent staining.

Binding assays, complement-dependent and cell-dependent cytotoxicity assays.—IIF assay was performed as described in (*8*). Acetone-fixed 4-µm cryostat sections of surgically removed tissues were overlayed with 5 µg MoAb 376.96S/ml for 30 minutes at 25°C. After washing for 5 minutes in cold PBS, we applied FITC rabbit anti-mouse Ig antiserum for an additional 30 minutes. After a final wash with cold PBS, the sections were mounted in PBS-buffered glycerol and observed with a Leitz Ortholux II fluorescence microscope equipped for phase-contrast microscopy and with epillumination. We used the distinct bright green fluorescent staining of the plasma membrane as a criterion of positive reactions of tissue sections with monoclonal antibodies. As a control, we tested unreactive tissue sections with concentrated, 20-µg/ml solutions, and diluted 0.5-µg/ml solutions of monoclonal antibodies to avoid false-negative reactions attributable to either a low concentration of the monoclonal antibodies or to a prozone-like effect (*14*). The specificity of fluorescent staining was controlled by testing tissue sections with myeloma protein secreted by the murine myeloma cells P3-X63-Ag8 and with culture supernatants of the hybridomas 376.96S from which the monoclonal antibodies had been removed by adsorption at 4°C with one volume of cultured human melanoma cells M10. The efficiency of adsorption was confirmed by the failure of the adsorbed culture supernatant to stain cultured human melanoma cells.

We performed the ^{125}I-labeled SpA radioimmunometric assay in microtiter plates as described elsewhere (*15*). The complement-dependent cytotoxicity test was done as an eosin-exclusion test with the use of rabbit serum as a complement source (*16*).

ADCC assay was performed in 96-well Microtiter plates (Cooke Laboratory Products Div., Dynatech Laboratories, Inc., Alexandria, Va.) with murine splenocytes as effectors (*17*). The percentage of specific ^{51}Cr release from the cells was used as a measure of lysis and was calculated as follows: $\%\ \mathrm{ADCC} = (A-B)-(C-B)/(T-B)-(C-B)\times 100$, where A=mean cpm of test samples, B=mean cpm of counter background, C=mean cpm of antibody-free control in the presence of effector cells, and T=mean cpm of total amount of ^{51}Cr incorporated into the target cells. We performed all test combinations in triplicate; the spontaneous or background leakage of ^{51}Cr from the target cells ranged from 13 to 21% of the total incorporated radiolabel.

Indirect immunoprecipitation, sequential immunoprecipitation SDS-PAGE.—Indirect immunoprecipitation and sequential immunoprecipitation were performed as described previously (*18*) except that protein A–Sepharose 4B was used in place of the Formalin-fixed bacteria and preclearing of the NP-40 detergent cell extract was not necessary. SDS–PAGE was performed in 90×1.5-mm slab gels containing an acrylamide gradient of 5–12.5% and the SDS buffer system of Laemmli (*19*). The gels containing [^{3}H]glucosamine-labeled antigens were processed for fluorography as described by Bonner and Laskey (*20*). Rabbit phosphorylase a (MM 94,000), bovine serum albumin (MM 68,000), ovalbumin (MM 44,000), carbonic anhydrase (MM 29,000) and whale myoglobin HM 17,000 were used as standards.

RESULTS

Structural Profile of the Antigen Recognized by MoAb 376.96S

Indirect immunoprecipitation of [^{3}H]glucosamine-labeled BwV or COLO 38 melanoma cell extracts with MoAb 376.96S revealed a single component having an apparent MM of 94,000 daltons (fig. 1). A component with the same apparent MM was also immunoprecipitated from ^{125}I-labeled COLO 38 melanoma cells, which indicated the existence of both carbohydrate and protein moieties in this molecule. In addition, a 94,000-dalton molecule was immunoprecipitated by the MoAb 376.96S from the urinary bladder carcinoma cell lines MANO and T24 and the prostate carcinoma line H494 but not from the cultured B-lymphoid cell Raji and the cultured T-lymphoid cell 1301 (fig. 1). The apparent MM of the 94,000-dalton antigen did not change when SDS–PAGE was performed in the absence of 2-mercaptoethanol. The molecule could be readily solubilized under mildly dissociating conditions (10 m*M* phosphate buffer, 3 *M* KCl, 0.1 *M* urea) and in the absence of detergents.

The structure recognized by the MoAb 376.96S is antigenically unrelated to the 94,000-dalton component identi-

TABLE 1.—*Reactivity of MoAb 376.96S with normal human tissues assessed by IIF assay*

Reactivity	Normal tissues
Negative	Brain cortex, colon, endometrium, fat tissue, gallbladder, kidney, lung, lymph node, mammary gland, skin from perineum, spleen, sympathetic ganglia, testis, thymus, urinary bladder, rectum
Very weakly stained	Stomach epithelium, limited areas of the epidermal basal layer from skin of the neck and abdomen.

fied by the MoAb 465.12S, since in sequential immunodepletion experiments neither of the antibodies was able to deplete the 94,000-dalton structure detected by the other antibody (fig. 2). Also, immunodepletion experiments performed with a limited amount of the MoAb I_{12}, provided by Dr. Dippold and colleagues, Sloan-Kettering Institute, New York, N.Y., indicate that this monoclonal antibody and the MoAb 376.96S recognize antigenically distinct structures (fig. 3).

Pattern of Reactivity of MoAb 376.96S With Surgically Removed Normal and Tumor Tissues

The results of the screening of MoAb 376.96S on fresh normal and tumor tissues by IIF are summarized in table 1. The MoAb 376.96S failed to stain a variety of normal tissue sections except sections of stomach epithelium and limited areas of the epidermal basal layer from the skin of the neck and the abdomen. The staining of the tissues was very faint, barely detectable with the oil-immersion objective of the fluorescence microscope. Among benign lesions of the skin, the MoAb 376.96S stained a high proportion of intradermal nevi (3 of 6 cases) and compound nevi (5 of 8 cases), whereas 6 cases of blue nevi and 6 cases of pigmented skin lesions (sebaceous warts, sclerosing angioma, and keratoacanthoma) were negative. Conversely, the incidence and the intensity of staining were found to be highly increased when pathologic lesions and tumors were tested with the MoAb 376.96S (table 2). The most reactive group with the monoclonal antibody was the melanoma group, where 83% (15 of 18 cases) of primary lesions arising from the superficial spreading, malignant lentigo, and nodular type lesions exhibited bright green fluorescence of the plasma membrane (fig. 4).

The monoclonal antibody stained only 65% of metastatic melanomas (13 of 20 cases), and the fluorescence was less bright than that found in primary tumors. The staining pattern observed in both primary and metastatic melanomas was independent of melanin content and showed a high degree of heterogeneity within each lesion as it ranged from negative reactions to very bright staining. A high percentage of skin carcinomas (6 of 12 cases of basal cell and squamous cell carcinomas) were reactive in the IIF test and were most noted for a great variation in staining intensity among the various specimens. For tumors other than those from the skin, the MoAb 376.96S was reactive with 22% of the breast carcinomas (10 of 45 cases) including infiltrating ductal, medullary, lobular type, and their metastases, and with one case each of rectum adenocarcinoma, glioblastoma, transitional cell carcinoma of the urinary bladder, and liver adenoma. In these cases, most of the tumor tissues tested showed a variable degree of staining in which only some areas of the tumor cell plasma membranes were brightly stained.

TABLE 2.—*Reactivity of MoAb 376.96S with human tumor tissues assessed by IIF assay*

Tumors	No. positive/No. tested
Primary melanoma	15/18

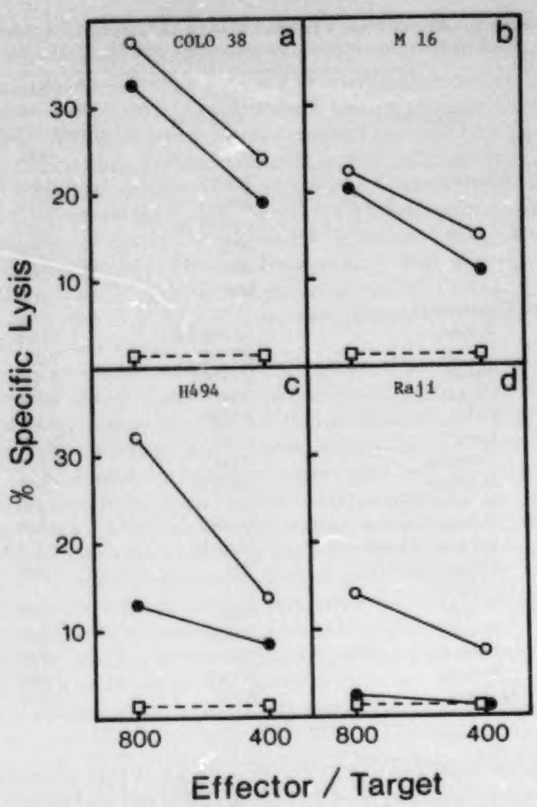
Serologic Reactivity of the MoAb 376.96S With Cultured Human Cell Lines

The MoAb 376.96S was tested in a ^{125}I-labeled radioimmunometric binding assay to compare the level of the 94,000-dalton glycoprotein expressed by different types of cultured human cell lines (table 3). The MoAb 376.96S bound in considerable amounts to most of the melanoma cell lines and also reacted with 9 of 10 carcinoma cell lines, but it was unreactive with cultured lymphoid cells. The prostate carcinoma line H494 was unusual in that it expressed more than double the level of antigen detectable on the next most reactive carcinoma or melanoma cell line. The same pattern of reaction of the MoAb 376.96S was also obtained in the adsorption test and in the indirect immunofluorescence assay with staining detectable at the plasma membrane but not in cytoplasm of the cultured cells.



TEXT-FIGURE 1.—Antibody-mediated cell-dependent lysis of various cell lines with the MoAb 376.96S and mouse splenocytes. Microtiter plates (96 wells) containing 4×10^3 ^{51}Cr-labeled melanoma cells (COLO 38 and M16), prostate carcinoma cells (H494), and the B-lymphoid cells (Raji) were first incubated with MoAb 376.96S (●——●), 345.134S (○——○), or Sp2-O myeloma supernatant (□- - -□) prior to addition of murine C3H/HeN splenocytes. After 18 hr of incubation, the supernatants were harvested and counted in a gamma counter, and the percent of ^{51}Cr release was determined.

The MoAb 376.96S mediates complement-dependent and cell-dependent lysis of cultured melanoma and carcinoma cells; results of representative experiments are shown in text-figure 1. In contrast, the antibody does not mediate immune lysis of cultured lymphoid cells. They are, however, susceptible to complement-dependent and cell-dependent lysis mediated by the MoAb 345.134 which recognizes an antigenic structure unrelated to that identified by the MoAb 376.96S.

DISCUSSION

We described a 94,000-dalton plasma membrane glycoprotein absent from the large majority of normal human tissues but readily detectable in human melanomas and lesions of the skin and in some breast carcinomas; some rare positive cases were noted for tumors of the brain and gastrointestinal tract. Immunochemical analysis with cultured melanoma and carcinoma cell lines indicates that the 94,000-dalton structure is not disulfide-bridged in its native state and is peripheral rather than integral in its association with the plasma cell membrane. The second conclusion is based on the ability to solubilize the 94,000-dalton component from melanoma cells in the absence of detergents. Serologic analysis with cultured human cell lines showed that MoAb 376.96S can mediate complement-dependent and cell-dependent cytotoxicity in a fashion that parallels the cell surface expression of the 94,000-dalton target antigen.

The size and tissue distribution of the glycoprotein detected by MoAb 376.96S are similar to those of the antigens described by Brown et al. (*21*) and Dippold et al. (*4*). However, as shown here, the monoclonal antibody provided by Dr. Dippold and his colleagues reacts with a molecule different than the one detected by our monoclonal antibody. The apparent molecular weight of the structure detected by Dr. Dippold's antibody is slightly lower than that of our 94,000-dalton structure. As yet, we cannot assess the relationship between our reagent and the one reported by Brown et al. (*21*) since the reagent has not been made available to us. Exchange of monoclonal antibodies through workshops sponsored by the National Institutes of Health will greatly benefit these types of comparative analyses. The 94,000-dalton structure identified by the MoAb 376.96S also differs from that described by Mitchell et al. (*6*) since the latter is not detectable on nevi (*22*) and carcinoma cells and is associated with three other glycopolypeptides. Finally, the 94,000-dalton structure detected by MoAb 376.96S differs in tissue distribution and in antigenic and molecular profile from the cytoplasmic antigen identified by our MoAb 465.12 (*9*).

The MoAb 376.96 could mediate complement-dependent and cell-dependent lysis of both melanoma and carcinoma cells. The MoAb 225.28S to a high-molecular-weight melanoma-associated antigen could mediate cell-dependent lysis but not complement-dependent lysis of melanoma cells (Imai K, Pellegrino MA, Wilson BS, Ferrone S: Submitted for publication), even though it is of the same IgG subclass as the MoAb 376.96S (IgG2a) and the corresponding target antigen is expressed at a level similar to that of the target antigen recognized by the MoAb 376.96S. These results indicate that factors other than antigen density and antibody subclass play a crucial role in the outcome of immune lytic reactions. This contention is also supported by the finding that a significant increase in the extent of immune lysis mediated by the MoAb 376.96 can occur when melanoma cells are treated with low concentrations of puromycin which do not effect the level of expression of the 94,000-dalton target structure (Imai K, Ferrone S: Unpublished observations).

The 94,000-dalton glycoprotein described in this study shares several features with other membrane-bound and cytoplasmic antigens we have identified in human melanoma cells with monoclonal antibodies. These include a high-molecular-weight membrane-bound antigen (*9*), an 85,000-dalton membrane-bound glycoprotein (*10*), a four-chain cytoplasmic antigen (*9*), and Ia antigens (*23*) which are the human counterparts of the murine I-E subregion antigens (*24*). The 94,000-dalton glycoprotein described in this study, the high molecular weight antigen, the 85,000-dalton antigen, and the cytoplasmic antigen are similar in their distribution on cells of the melanocyte lineage since they are not detectable on melanocytes but are expressed by nevi and melanoma cells (*9*). Conversely, Ia antigens have a more restricted distribution since they are detectable only on melanocytes which have undergone malignant transformation (*8*). Additional common features of the 94,000-dalton glycoprotein and the other markers we have identified are 1) presence in both primary and metastatic lesions (*8, 9*), and 2) heterogeneous expression within cells of a single melanoma lesion and/or among different lesions (*8, 9*). The second finding raises the possibility that a successful application of monoclonal antibodies to tumor-associated antigens in the area of radioimaging and immunotherapy may require the use of a cocktail of monoclonal antibodies to distinct tumor-associated antigens to detect or eliminate tumor cells with little or no expression of a given determinant.

ABSTRACT—The in situ two-step collagenase perfusion technique used for the isolation of hepatocytes from rat liver was adapted into a procedure applicable to pieces of human liver obtainable from surgical procedures. Human hepatocytes obtained by this method were maintained in primary culture for 10 days. The cellular changes observed at the light microscopic and electron microscopic levels are described. The changes in microsomal enzymes as a function of the age of the cultures were also measured. Exposure of the human hepatocytes to procarcinogens known to be metabolized by rodent liver resulted in unscheduled DNA synthesis. The isolated hepatocytes were also transplanted into two-thirds partially hepatectomized athymic nude mice. The transplanted cells formed nodules with characteristic hepatic architecture. These studies demonstrate that hepatocytes obtained from human liver by the described modified collagenase technique can be used for in vitro studies in chemical carcinogenesis.—JNCI 1982; 68:771–778.

The technique of the two-step in situ collagenase perfusion, originally introduced by Berry and Friend (*1*) and modified by Seglen (*2*), is a widely used method for obtaining viable dispersed hepatocytes from adult rat liver. The perfusate is introduced through vascular pathways, and the completion of the procedure results in dissociated liver tissue that can be further dispersed into isolated hepatocytes by simple mechanical means. The isolated hepatocytes can be used in vitro either as a suspension (*2*) or in primary culture (*3–6*). Additionally, the liver cells can be transplanted into syngeneic recipient animals (*7–9*). The main advantage of this collagenase dissociation procedure is that it results in a large number of cells with excellent viability. Thus multiple replicate samples from a single liver can be utilized for a variety of applications.

Studies utilizing a large number of intact human hepatocytes have thus far been limited because of the inability to adapt the in situ collagenase perfusion technique to human liver. The difficulties have been mainly technical, since large quantities of collagenase and perfusate are required to scale up this technique for the human liver. In previous reports fragments of human liver tissue from needle biopsies have been placed in explant culture (*10*). However, the small sample size severely restricts the experimentations that can be performed, and multiple replicate samples cannot be obtained. Primary cultures of adult human hepatocytes, analogous to those of adult rat hepatocytes, would require a large number of viable cells. Establishment of the methods for such primary cultures would be applicable to experimental studies involving a variety of disciplines. Primary cultures of human hepatocytes can be of use in studies related to the effects of chemical carcinogens on human tissues and the interspecies comparisons between, for example, humans and rodents. They may provide the ideal substrate for the culture of the various hepatitis viruses. They could also be used in the studies of intermediary human hepatic metabolism and physiology.

We (*7*) and others (*8*) have recently described systems of transplantation of adult rat parenchymal hepatocytes. After transplantation the hepatocytes proliferate and become organized into a structure that is similar to the one found in the liver. We have used this transplantation system to quantify the effects of genotoxic agents on rat hepatocytes (*11*) and to investigate the mechanism of liver regeneration (*12*). If adult human hepatocytes could be stimulated to proliferate when transplanted into athymic nude mice, the probability of cell survival and neoplastic transformation after cellular exposure to genotoxic agents could be quantified in a manner similar to that developed for rat hepatocytes.

In this report we describe a modified version of the in situ collagenase perfusion technique that can be applied to fragments of human liver tissue. This approach obviates the logistic difficulties in the use of an intact human liver. The method uses quantities of collagenase and perfusate, for example, that are on a scale analogous to the one used in the in situ perfusions of rat liver. We further describe properties of these isolated human hepatocytes in terms of their morphology in primary culture, their microsomal enzyme levels, and the UDS measured when these hepatocytes are exposed to procarcinogens. The morphology of human hepatocytes transplanted into nude mice is also described.

MATERIALS AND METHODS

Materials.—Collagenase II was obtained from Worthington Biochemical Corp. (Freehold, N.J.) from lots that were

tested in terms of their capacity to produce viable hepatocytes from adult rat liver. Tissue culture media were obtained from Grand Island Biological Co. (Grand Island, N.Y.). Athymic nude mice were obtained from Charles River Breeding Laboratories (Wilmington, Mass.). Chemicals were purchased from Sigma Chemical Co. (St. Louis, Mo.) unless otherwise specified.

Perfusion technique.—Pieces of canine liver were obtained from dogs used for a variety of experiments not directly involving the liver. Hepatic tissue was removed within 5 minutes after cessation of cardiac function. The perfusions of canine liver fragments were performed to define the conditions that would allow perfusions of fragments of human liver. The conditions described below for the fragments of human liver reflect the accumulated experience with multiple perfusions of canine liver fragments. Human hepatic tissue fragments were obtained from discarded surgical material removed from two patients during scheduled surgical procedures.

In the first case a right lobectomy was performed for the removal of a solitary neoplastic lesion metastatic from colon adenocarcinoma in a 62-year-old white female. In the second case a right lobectomy was performed in a 14-year-old male for the removal of a lesion later diagnosed as fibromyxosarcoma. In both cases the right lobe of the liver was brought for pathologic examination within 20 minutes after ligation of the right portal vein and hepatic artery branches. The location of the neoplastic lesion was identified, and sections were taken to establish histopathologic diagnosis. The diameter of the neoplastic lesion by gross criteria did not exceed 5 cm. Hepatic tissue was removed from the periphery of the discarded material and at a distance of at least 5 cm from the periphery of the neoplastic lesion. Care was taken to ensure that the removed pieces were surrounded by a hepatic capsule on all sides except for one cut surface. The thickness between the edge of the capsule and the exposed cut surface did not exceed 2 cm. The largest of the liver pieces did not exceed 3.5 cm in width. The weight range for the pieces was between 6 and 12 g. The tissue pieces were placed in ice-cold saline and transported to the perfusion site. Plastic polyethylene catheters (18-gauge or smaller) were inserted into every vascular orifice that could be identified on the cut surface (from 3 to 5/piece). The tissue pieces were then perfused with a calcium-free buffer. One liter of the buffer contained potassium chloride (0.5 g), sodium chloride (8.3 g), and HEPES[10] buffer (2.4 g) (*13*). The pH of the buffer had been previously adjusted to 7.4 with sodium hydroxide. The flow rate was adjusted to 14 ml/minute/catheter. The perfusate was allowed to drain and was not recirculated. After 20 minutes the perfusion buffer was changed to one of identical composition to that described above with the addition of calcium chloride ($CaCl_2 \cdot 2H_2O$) at a concentration of 74 mg/liter and collagenase at a concentration of 0.5 mg/ml of buffer. The collagenase solution was perfused at an identical rate and for the same time as those used for the calcium-free buffer. The perfusion buffers were delivered to the hepatic fragments at a temperature of 37°C. The temperature at the delivery site (one of the blanched areas) was measured with a thermistor probe connected to a digital thermocouple thermometer (model bat 8; Bailey Instruments Co., Inc., Saddle Brook, N.J.). Previous experience with the canine liver and with rat liver perfusions indicated that there is at least a temperature loss of 5°C along 40 mm of silicone tubing (≈3–5 mm in diameter). For these perfusions (and for all rat liver perfusions in our laboratory), the perfusate container is maintained at 42°C so that a delivery temperature of 37°C to the liver is maintained.

As soon as the perfusion was started, it was observed that wedge-shaped areas on the surface of each liver piece began to blanch (fig. 1). The blanched areas covered approximately 70% of the surface of each fragment. At the end of the perfusion process, the liver pieces (blanched and nonblanched areas) were minced with a scissors into fragments less than 1 mm in diameter. The resultant minced material was filtered through a nylon mesh filter (150-μm pore size). The cellular suspension was washed in ice-cold calcium-free buffer and centrifuged for 2 minutes at 50×*g*. The washing procedure was repeated three times. The total yield of isolated hepatocytes was approximately 50×10^6 cells/g of liver. A viability test of trypan blue exclusion indicated that more than 70% of the hepatocytes excluded the dye.

Culture methods.—The isolated hepatocytes were suspended in minimum essential medium with Earle's salts supplemented with insulin (10^{-7} *M*), fetal bovine serum (10%), and gentamicin (50 μg/ml). The cells were inoculated into collagen-coated (*5, 14*) 60-mm-diameter tissue culture plates at a density of 3.5×10^6 cells/plate. Although previous studies (*14*) have shown that higher levels of cytochrome P_{450} can be maintained in hepatocytes on collagen gels, collagen-coated substrates as compared to collagen gels can be more easily used for autoradiography and were the substrate of choice in these studies. The medium (5 ml/plate) was changed 4 hours after hepatocyte inoculation and every 24 hours thereafter. Phase-contrast microscopy of the cells at days 1–5 indicated that less than 3% of the cells were nonparenchymal, in agreement with previous reports (*2*). We calculated the percent of attached cells by dividing the measured DNA content of the cells attached to the plates at various time points by that of the total DNA in the initial inoculated sample. The DNA content was measured according to the method of Setaro and Morley (*15*).

Measurement of microsomal enzymes.—Cytochrome P_{450} and cytochrome *b*5 were measured according to the method of Omura and Sato (*16*). NADPH–cytochrome *c* reductase was measured according to the method of Phillips and Langdon (*17*).

Measurement of UDS.—Autoradiographies were performed for the measurement of UDS according to the method of Williams (*18*) and Probst et al. (*19*). Hepatocytes were cultured in collagen-coated eight-chamber slides (Lab-Tek Products, Div. Miles Laboratories Inc., Naperville, Ill.). These slides allow comparison of replicate (eight) cultures, on the same microscope slide with each culture exposed to different procarcinogens. After exposure of each chamber culture for 20 hours (from 4 to 24 hr in culture age) to medium supplemented with [^{3}H]thymidine (10 μCi/ml) and with solvent (control) or a specific concentration of procarcinogen, the chamber walls were removed, and the slides were extensively washed and finally coated under safe lights with a thin layer of undiluted Kodak NTB-3 emulsion. The slides were kept in the dark at room temperature for 10 days. They were subsequently developed and stained with hematoxylin and eosin.

---

[10] 4-(2-Hydroxyethyl)-1-piperazine ethanesulfonic acid.

Electron microscopic procedures.—The specimens were fixed in the plate in 4% glutaraldehyde (buffered with 0.1 *M* sodium cacodylate), postfixed in 1% osmium tetroxide, and stained with uranyl acetate. Cells were embedded in Epon and lifted off the plate. Sections were taken through the Epon-embedded cells. The final sections (500–600 Å thick) were stained with 4% acetate and Reynold's stain.

Transplantation into nude mice.—The methods for transplantation were similar to those previously described for rats (*7*), except for the omission of brain homogenate. Human hepatocytes (5×10^5) were injected into the interscapular fat pads of athymic nude mice. The nude mice had been subjected to a two-thirds partial hepatectomy 1 hour prior to hepatocyte injection. The animals were killed 20 days after transplantation, and the fat pads were removed and processed as previously described (*7*).

RESULTS

Of the cells inoculated into collagen-coated plates, 42% remained attached after 24 hours and two medium changes. These results are comparable to those seen for rat hepatocytes (*3–6*). Examination of the cultured hepatocyte monolayers by phase-contrast microscopy at 4 hours after inoculation showed that the hepatocytes had attached to the collagen substrate in small groups composed of two or three cells, but they still had a rounded contour. At 24 hours after inoculation, most cells had spread out and formed a continuous monolayer (fig. 2). Each cell had a refractile, round nucleus with a prominent nucleolus. The cytoplasm had a fine granularity with the occasional appearance of small refractile droplets, probably of lipid origin. The epithelial morphology of the cells was maintained for at least 10 days in culture. As with primary cultures of rat hepatocytes, no evidence of hepatocellular growth was observed.

Samples of the monolayer cultures were taken at day 1 and processed for electron microscopy. A typical appearance of a human hepatocyte in culture on day 1 is shown in figure 4. Large numbers of oblong mitochondria, RER, and prominent SER were seen. Desmosomes were noted in the opposing surfaces of adjacent hepatocytes. Structures analogous to bile canaliculi were not noted. These structures have been shown to be maintained in rat hepatocytes when cultured on floating collagen membranes, but not when cultured on a rigid substrate (*20*). Large numbers of vesicles of SER were seen in the hepatocytes from the first case, especially at day 1. Such a change is classically induced experimentally with phenobarbital, but it can also be induced by large number of drugs, toxins, and nutritional disorders. The medications given to patient #1 preoperatively included 5-fluorouracil, diazepam, and acetaminophen. In electron microscopic studies of needle biopsy specimens from human liver, a similar increase in SER was noticed in patients given diazepam (*21*). Such a change was not seen in hepatocytes obtained from patient #2.

Table 1.—*Microsomal enzyme levels as a function of time in culture*[a]

Time in culture, days	Cytochrome P_{450}	Cytochrome *b*5	NADPH-cytochrome *c* reductase
		Case 1	
0	1,380 (100)	2,354 (100)	0.279 (100)
1	785 (58)	963 (41)	0.247 (89)
4	758 (55)	617 (26)	0.352 (126)
		Case 2	
0	970 (100)	392 (100)	0.177 (100)
1	670 (69)	474 (121)	0.235 (133)
4	541 (56)	276 (70)	0.148 (84)

[a] The absolute values indicate picomoles of cytochrome per milligram of microsomal protein or units of reductase per milligram of microsomal protein. *Numbers in parentheses* are percentages of the values measured in the human hepatocytes immediately after the collagenase perfusion (time 0 sample).

[b] NS=not significantly different from control. Statistical analysis was performed with the use of Student's *t*-test.

[c] Significantly different from control at $P<0.01$.

[d] $P<0.02$.

Monolayer cultures from both cases were also processed for measurements of microsomal enzymes. The data shown in table 1 express the measured values of the indicated parameters in absolute numbers as well as percentages of the values seen in the isolated hepatocytes immediately after the perfusion. For both cases as an average, the cytochrome P_{450} levels after 24 hours in culture were approximately 60% of those for cells immediately after perfusion. Furthermore, the cytochrome P_{450} levels declined only slightly between days 1 and 4 in culture.

UDS was measured in autoradiographs performed as described in "Materials and Methods." The procarcinogens used were chosen from compounds that are known to be metabolized and result in UDS in primary cultures of rat hepatocytes (*19*). The data obtained are shown separately for the two cases in table 2.

When human hepatocytes were injected into the intercapsular fat pads of two-thirds hepatectomized athymic nude mice, hepatocyte nodule formation was observed (fig. 3). The cells maintained a morphologic appearance characteristic of hepatocytes, and the nodule formation was analogous to that seen when rat hepatocytes are transplanted into either syngeneic recipient animals (*7*) or athymic nude mice (Michalopoulos G, Strom SC, Jirtle RL: Unpublished data).

DISCUSSION

Quantitative analysis of the effects of chemical carcinogens on cells or tissues of human origin is essential for ultimate assessment of carcinogenic risk in humans and for interspecies comparisons between humans and other species mostly applied in assaying carcinogenicity (rodents). Studies pursuing this approach have been previously presented with replicating cell lines (*22*) or strains of human fibroblasts alone (*23*) or in combination with hepatocytes (*24*). Analogous studies have been extensively conducted in organ cultures of human bronchus (*25*). These studies have demonstrated the capacity of the human bronchus to provide metabolic activation for a wide variety of carcinogens previously recognized as respiratory carcinogens for the rodents.

Studies with human hepatocytes have lagged due to the lack of a feasible technique that can be applied to human liver and result in large numbers of viable hepatocytes, in a way analogous to the case of the two-step collagenase perfusion extensively characterized for rat liver (*2*). The results shown in the present report demonstrate that with use of the modified in situ collagenase perfusion technique, large numbers of viable adult hepatocytes can be obtained that are suitable for primary culture and transplantation into athymic nude mice. The results presented here are not a comprehensive analysis of all the possible studies that could be performed to fully characterize the morphological and biochemical properties of human hepatocytes in primary culture or in transplantation. To our knowledge, however, this is the first incidence where large numbers of viable hepatocytes have been isolated and replicate samples analyzed from a single piece of human liver. The data presented also demonstrate the feasibility of adapting to human hepatocytes the techniques developed for culturing and transplanting rat hepatocytes.

The technique of collagenase perfusion, as described in this report, can be scaled and adjusted for liver fragments of different sizes. In previous studies with dog liver (Michalopoulos G, Strom SC, Jirtle RL: Unpublished results), we observed the highest yield of viable hepatocytes when the fragments were perfused at a flow rate of 14 ml/minute/catheter. We consider it an essential point of the technique to perfuse fragments surrounded entirely by the hepatic capsule with only one cut surface. This configuration forces the perfusate to flow back through the cut surface and perfuse areas whose vascularity is dependent on the vessels of the cut surface. Hepatic tissue sufficiently viable to be amenable to the described procedure can be obtained from organ donors or from scheduled hepatic resections. Hepatic lobectomy (right or left lobe) is frequently performed to remove solitary metastatic lesions resulting from primary neoplasms already resected in the past. For reasons relating to easy hemostasis and tumor containment, it is preferrable to remove the whole lobe that contains the tumor rather than to just enucleate the tumor with a rim of hepatic tissue. Since the remaining liver lobe regenerates to reconstitute total hepatic mass within 10 days, the size of liver tissue removed (when at least one lobe remains) is not of critical importance. The resulting specimen brought into the surgical pathology laboratory usually contains more hepatic tissue than needed for the establishment of diagnosis. The residual excess tissue (normally discarded) can be utilized for the procedure presented in this report. The uniqueness of this procedure is that it applies to larger fragments of hepatic tissue, so that numbers of hepatocytes sufficient for multiple replicate experimental points can be obtained. Previous procedures applicable to needle biopsies or small wedge biopsies (*9*) have already been described.

The main limitations of those systems were that the resulting number of hepatocytes were too small and the viability was not high enough. Most important, however, is the fact that the small wedge or needle biopsy procedures did not utilize hepatic tissue that would be otherwise discarded, but rather they were applicable to hepatic tissue fragments that, in most instances, need to be processed in toto for diagnostic purposes. Such pieces are not routinely available for research purposes due to restrictions justafiably imposed by ethics committees. Such restrictions, however, usually do not apply to tissue that will definitely be otherwise discarded and is not of diagnostic use. This technique, with the details presented in "Materials and Methods," was so far successful in both of the only two instances that we applied it for the purposes of this report.

The measurement of UDS by autoradiography as described by Williams (*18*) is particularly suitable for human hepatocytes in that it can be adapted for use with small samples. Each of the chambers of an eight-chamber slide has an area of $1\ \text{cm}^2$, which allows up to 100,000 hepatocytes to be individually evaluated by counting of the grains per nucleus as previously described (*17, 18*).

The results obtained from the studies with UDS (table 2) indicate that the hepatocytes can metabolize the procarcinogens to active genotoxic metabolites which then react with DNA. The UDS assay used indicates the amount of DNA synthesis that takes place to fill the gaps generated during the excision repair process. 2-FAA was a good inducer of UDS in both cases. Nitrosamines also induced UDS in both cases. In both cases, lesser degrees of UDS were seen with BP than with 2-FAA at equivalent concentrations. Although it is premature to generalize from these two cases, the observed rank order of maximal induced UDS for the four carcinogens (2-FAA>nitrosamines>BP) correlates well with the observed rank described in rat hepatocyte monolayer systems by Williams (*18*), by Tong et al. (*26*), and by us (*27*). More cases are necessary to give us an estimate of the range of variation of these responses in the human population. The preliminary results of this report do point out, however, interesting similarities between rat and human hepatocytes in terms of their responses to these carcinogens.

Differences in the degree of response to the same concentrations of chemicals were seen between the two cases (e.g., dimethylnitrosamine). These differences may reflect patterns of expression of hepatic microsomal or cytosol enzyme activities that are known to be affected by drugs, nutrients, sex, and age. All four of these factors differed in these two cases. An increase in membranes and vessicles of SER was seen in the first case. This change has been described (*21*) in patients after prolonged use of Valium (diazepam), as in this case. This change is also reflected in the higher levels of cytochrome P_{450} complex seen in the hepatocytes of the first case (table 1). The decrease in cytochrome P_{450} levels seen is analogous to that described for the rat hepatocytes (*14*). The decrease in cytochrome P_{450}, however, is much less in the cultures of human hepatocytes. At day 4 in culture, in both cases, more than 50% of the cytochrome P_{450} is still maintained. In similar cultures of rat hepatocytes, less than 10% of the original value of cytochrome P_{450} is still maintained at day 4. The reasons for these differences are not clear at the present time.

We have previously demonstrated that when rat hepatocytes are transplanted into syngeneic hosts, liver nodules develop with a characteristic hepatocyte histologic architecture (*7*). We have also shown that the nodules of hepatocytes at the site of transplantation arise as a result of clonal proliferation of hepatocytes. Analogous proliferation of cells is not seen in primary cultures. We have utilized the transplantation system to quantify the effects of ionizing radiation on the clonogenic survival of parenchymal rat hepatocytes (*11*). This assay system also enables the clonogenic survival of rat hepatocytes to be estimated after an in vitro exposure to mutagenic and carcinogenic compounds. Because of the results in figure 3, this in vivo clonogenic assay system may also be adapted for use with human hepatocytes. The transplantation of human hepatocytes into athymic nude mice, in a manner similar to that developed for rat hepatocytes, also may enable us to estimate the genotoxic effects of mutagenic and carcinogenic agents that are metabolized by the human liver. Full characterization of this system, in a way analogous to that of the rat system, will be attempted in future studies.

In conclusion, we have developed a modified version of the in situ collagenase perfusion technique that can be used to enzymatically disperse hepatocytes from pieces of human liver. These hepatocytes can be used for primary culture or transplantation. The studies with cytochrome P_{450} and UDS indicate that despite differences in sex, age, and exposure to drugs, common trends may be seen in human hepatocytes. These trends, in the case of cytochrome P_{450}, may be different than those seen with the rat. Accumulation of experience with a larger number of cases will allow comprehensive analysis of these trends and differences. These studies indicate that the collagenase perfusion technique presented in this report can result in production of large numbers of human hepatocytes from which replicate samples can be obtained for meaningful studies.

NOTE ADDED IN PROOF

Since this paper was accepted for publication, a similar technique for perfusing hepatic fragments was described by Reese and Byard (In Vitro 1981; 17:935–940).

Mitogen-Induced Blastogenesis and Receptor Mobility Inhibition by Breast Cancer Serum With Elevated Orosomucoid (α_1-Acid Glycoprotein) Levels[1,2,3]

David A. Cheresh,[4] John A. Distasio,[4,5,6] Charles L. Vogel,[5] *and* Diana M. Lopez[4,5,7]

ABSTRACT—Sera from cancer patients have been shown to suppress normal lymphoid cell responsiveness in vitro. In the present study, sera from breast cancer patients were demonstrated to be inhibitory to the concanavalin A (Con A)-, *Proteus vulgaris*-derived phytohemagglutinin-, and pokeweed mitogen-induced blastogenic responses of normal lymphoid cells. Orosomucoid (OR) (α_1-acid glycoprotein), an acute-phase reactant, was elevated in these sera, and a positive correlation existed between the OR level in the sera and its immunosuppressive capacity. When normal lymphoid cells were reacted in fluorescein isothiocyanate-labeled Con A, cells that had been preincubated in breast cancer sera known to contain an elevated level of OR showed a significant decrease in Con A receptor mobility as compared to the receptor mobility of the same lymphoid cells preincubated in normal sera. Thus a component(s) from the sera of breast cancer patients had the capacity to inhibit lymphocyte activation. This inhibition might have resulted from an interaction of OR with the cell membrane.—JNCI 1982; 68:779-783.

That breast cancer patients are immunologically compromised is well documented (*1-4*). Numerous studies have demonstrated reduced immune function, particularly in the patient with advanced-stage disease. Lymphoid cells from breast cancer patients have been shown to be deficient in their ability to serve as effector cells in cytotoxic reactions, to undergo blast transformation, and to mediate delayed-type hypersensitivity reactions (*1-4*).

We have recently reported that lymphoid cells from breast cancer patients with metastatic disease responded poorly in a Con A-induced blastogenic assay, as compared to cells of normal donors. With the use of the competitive inhibitor α-methyl-D-mannoside, we could maximize the difference in blastogenic response between lymphoid cells from healthy donors and lymphoid cells from cancer patients with early- as well as late-stage disease (*5*). Our study suggested that a membrane alteration on the lymphoid cells from these patients might affect Con A binding or Con A receptor affinity. In ^{125}I-labeled Con A binding studies, we were unable to detect an alteration in the average number of Con A receptors or the average receptor affinity for Con A on lymphocytes from metastatic breast cancer patients. Moreover, using FITC-labeled anti-Con A, we were unable to detect a difference in the number of cells capable of binding Con A (Schilder RJ, Distasio JA: Unpublished results).

In the present study, we investigated the possibility that a factor in sera from breast cancer patients may interact with lymphocyte membranes and alter their capacity to be stimulated by mitogen. Numerous reports in the literature have demonstrated the immunosuppressive potential of sera from cancer patients (*6-9*). The serum factor OR (α_1-acid glycoprotein) is a constituent of normal serum which is elevated in the acute phase of inflammation, neoplasia, rheumatoid arthritis, and pregnancy (*10, 11*). When OR is added to normal lymphoid cells in culture, it is capable of inhibiting mitogen-induced blast transformation, mixed lymphocyte responses, and cytotoxic reactions (*12, 13*). OR is a glycoprotein (mol wt, 41,000), 42% of which is carbohydrate. It has a high (10-12%) sialic acid content (*14*) and is composed of 181 amino acids, which have significant sequence homology to the constant and variable portions of immunoglobulin (*15*). OR has been shown to be associated with the membranes of lymphocytes, monocytes, and granulocytes (*16*). While liver is the primary site of OR synthesis and secretion, a recent study indicates that OR is also secreted by T-lymphocytes (*16*). Thus it seems plausible that OR may serve as an immunoregulatory molecule.

In the present study, we examined the effects of sera from metastatic breast cancer patients on the activation of lymphoid cells from normal donors. We show a positive correlation between the OR level and the immunosuppressive potential of the sera. We also demonstrate that breast cancer patients' sera known to have an elevated level of OR are capable of inhibiting Con A receptor mobility. These findings indicate that a lymphocyte membrane alteration is induced by the serum of the breast cancer patient and that OR may be the responsible factor.

[7] We thank Ms. Dawn East and Ms. Margaret Szaro (University of Miami Hospitals and Clinics) for identifying suitable patients for our study, confirming clinical characteristics of patients, and obtaining the blood; and Dr. Karl Schmid (Department of Biochemistry, School of Medicine, Boston University, Boston Mass.) for providing the purified orosomucoid that was used as the standard in this study. We give special thanks to Mrs. Frances Susi for typing the manuscript.

MATERIALS AND METHODS

Patient population.—Sera were collected from 25 women with metastatic breast cancer. The following staging procedures were done for each woman before she was entered into this study: complete medical history, physical examination, and blood and platelet counts; liver function tests; plasma carcinoembryonic antigen assay; chest X-ray; liver and bone radionuclide scans; and confirmatory bone X-rays of bone scan-positive areas. All of the patients were shown to have local, regional, or distant metastases. No patient receiving systemic therapy for cancer within the past year was entered into the study. Excluded from the study were patients who had received radiation therapy and patients with a history of diabetes mellitus, alcoholism, rheumatoid arthritis, or any other chronic condition. The mean age of the patients was 58.0 years (range, 30–77 yr). Sera were collected from 28 healthy women for use in control assays. The mean age of the normal donors was 52.3 years (range, 23–70 yr).

Collection of sera.—Blood was obtained by venipuncture and was allowed to clot for 2 hours at room temperature. The sera were separated from the clots by centrifugation at 1,000×*g* for 15 minutes. The sera were allowed to stand at room temperature for 24 hours, which inactivated complement, and the complement-inactivated sera were then stored at 4°C until use.

Quantitation of serum OR.—Serum levels of OR were determined by the Mancini single radial immunodiffusion method (*17*). Goat anti-OR (Miles Laboratories, Inc., Elkhart, Ind.) was diluted 1:5 with PBS (pH 7.4). The diluted antibody was prewarmed to 50°C and mixed with equal parts of 2% agarose (liquefied) in a 0.1-*M* sodium barbital buffer (pH 8.4). The agarose–antibody solution was thoroughly mixed and poured between glass plates spaced 1 mm apart. After solidification, one glass plate was removed, and wells (2 mm in diameter) were punched in the gel. Diluted sera or solutions of OR standards (0.0625–1.0 mg/ml) were added in 3-µl amounts to triplicate wells, and diffusion was at room temperature in a humidified chamber for 48 hours. Precipitated rings were measured with calipers. Serum OR levels were compared to an OR standard curve that had been plotted as the diameter (mm) of the precipitin band as a function of the log of the OR concentration. OR used as the standard in this assay was provided by Dr. Karl Schmid, Boston University, Boston, Mass.

Isolation of mononuclear cells.—Peripheral blood mononuclear cells were obtained from healthy individuals with type O blood. Blood was obtained by venipuncture into syringes containing sufficient heparin (The Upjohn Co., Kalamazoo, Mich.) to yield a final concentration of 10 U/ml blood. Blood was diluted with an equal volume of sterile saline. Mononuclear cells were isolated by discontinuous density gradient centrifugation with LSM (Litton Bionetics Inc., Kensington, Md.). Diluted blood (20 ml) was layered over 15 ml of LSM. The gradients were spun at 400×*g* for 40 minutes at 19°C. Mononuclear cells were recovered from the interface and were washed three times with RPMI-1640 medium (GIBCO, Grand Island, N.Y.) supplemented with 100 U penicillin/ml and 50 µg streptomycin/ml (Associated Biomedic Systems, Inc., Buffalo, N.Y.). Washed cells were pelleted by centrifugation for 10 minutes at 25°C. Cells were resuspended appropriately for each assay as described below.

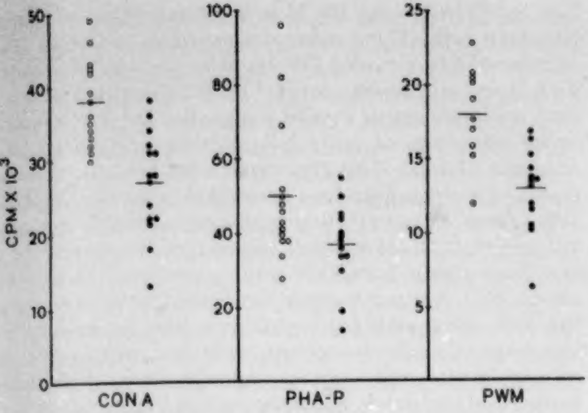
Blastogenesis assay.—Triplicate cultures were initiated in #3040 microtiter plates (Falcon Plastics, Los Angeles, Calif.) by the addition of 0.01 ml of each of the following solutions to each well of the plate: 0.5 mg Con A/ml (Calbiochem-Behring Corp., Los Angeles, Calif.), 0.1 mg PHA-P/ml (Difco Laboratories, Detroit, Mich.), or 0.5 mg PWM/ml (GIBCO). For control cultures, 0.01 ml of growth medium was added in place of mitogen. An additional 0.19 ml of growth medium supplemented with 10% human serum and containing 1×10^5 mononuclear cells was dispensed per well, and cultures were incubated for 72 hours in a 5% CO_2 humidified atmosphere. Eighteen hours before being harvested, cultures were pulsed with 0.01 ml of $[^3H]$thymidine solution (50 µCi/ml). A Skatron cell harvester (Flow Laboratories, Inc., Rockville, Md.) was used, and cells were collected on #78-105-05 glass fiber filter paper (Flow Laboratories, Inc.) and washed. Filter paper disks containing $[^3H]$DNA were placed in polyethylene vials with 5 ml of a scintillation cocktail of toluene containing 5 g 2,5-diphenyloxazole/liter and 0.2 g 1,4-bis[2-(5-phenyloxazolyl)]benzene/liter (Yorktown, Inc., Hackensack, N.J.). Vials were enumerated in a Tri-Carb liquid scintillation counter (model 3330; Packard Instrument Co., La Grange, Ill.). Data are presented as counts per minute of experimental cultures with mitogen less counts per minute of control cultures without mitogen.

Con A receptor mobility.—Mononuclear cells (2×10^6 cells) from a normal individual were incubated for 1 hour at 37°C in the presence of 0.2 ml of serum from a normal donor or breast cancer patient. The cells were washed once with $HBSS^-$. The cell pellet was resuspended in 0.2 ml FITC-Con A (Miles Laboratories, Inc.) (15 µg/ml) in $HBSS^-$. The incubation was done for 15 minutes in a 37°C water bath, after which time 0.2 ml of a 4% paraformaldehyde solution was added, thereby fixing the cells. We had previously determined that 15 minutes at 37°C was the optimal time for the fluorescent cells to demonstrate maximal capping under the conditions of this assay. After fixation, the cells were washed with PBS containing 1 mg bovine serum albumin/ml. Cells were then placed on a slide, and the number of cells with rings, patches, and caps was determined with a Nikon Optiphot microscope equipped with epifluorescence. Each slide was examined blindly, and a minimum of 200 cells/slide were counted. A cell was considered capped when the fluorescence was distributed uniformly over no more than one-third of the cell membrane. Cells with uropod formation were not counted.

Statistical analysis.—Data were analyzed by Student's *t*-test for unpaired random variables. A *P*-value of less than 0.05 was considered significant, and *r* were calculated by linear regression analysis.

RESULTS

Individual blastogenic responses of healthy donors' lymphoid cells incubated in the presence of sera from normal individuals (*n*=14) or sera from breast cancer patients (*n*=15) (hereafter called normal sera and breast cancer sera, respectively) were determined (text-fig. 1). The mean plus



TEXT-FIGURE 1.—Effect of normal or breast cancer sera on the Con A-, PHA-P-, and PWM-induced blastogenic response of normal lymphoid cells. ○=blastogenic response of lymphoid cells incubated in normal sera; ●=blastogenic response of lymphoid cells incubated in breast cancer sera. *Bars* represent mean blastogenic response in counts per minute. Effects of each serum tested were determined on lymphoid cells from 1 of 4 healthy donors. For additional experimental details, *see* "Materials and Methods."

or minus standard error for each response is recorded in table 1. In the presence of breast cancer sera, the mean Con A, PHA-P, and PWM mitogenic responses were inhibited approximately 29% ($P<0.001$), 26% ($P<0.05$), and 27% ($P<0.001$), respectively.

The serum OR concentrations of normal donors and breast cancer patients are compared in text-figure 2. In normal sera ($n=28$), the mean OR level was 0.77 mg/ml (range, 0.5–1.26 mg/ml). In the breast cancer sera ($n=25$), the mean OR level was 1.47 mg/ml (range, 0.64–2.65 mg/ml). Statistical analysis revealed that the breast cancer sera contained significantly elevated levels of OR ($P<0.001$).

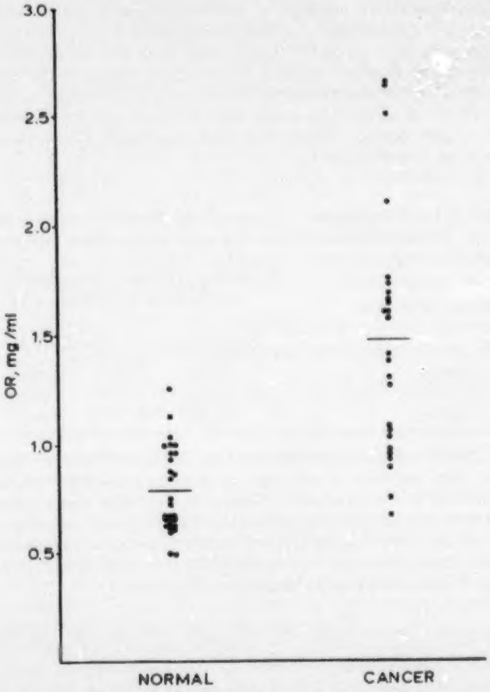
The correlation between the breast cancer serum OR level and its immunosuppressive capacity appears in text-figure 3. In each experiment the blastogenic responses of lymphocytes from healthy donors in the presence of serum from each patient was compared to the response in the presence of serum from a normal donor. The percentage of the blastogenic response of healthy donor's lymphocytes in the presence of breast cancer sera ($n=12$) as compared to the response in the presence of normal sera ($n=12$) is reported on the ordinate. The OR level of each breast cancer patient's serum is reported on the abscissa. The OR level of the cancer sera is negatively correlated with its capacity to support blast transformation. The r of the Con A-, PHA-P-, and PWM-induced blastogenic responses were −0.70, −0.63, and −0.53, respectively.

TABLE 1—*Blastogenic responses of lymphoid cells incubated in normal or breast cancer sera*[a]

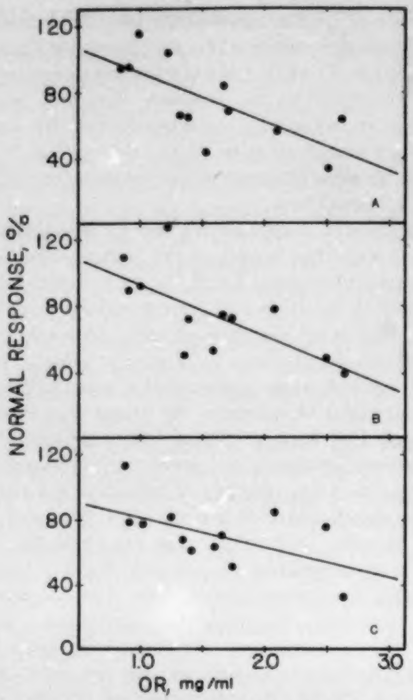
Mitogen	Mean cpm ± SE of cells incubated in:		Percent of normal response
	Normal sera	Breast cancer sera	
Con A	38,271±1,542	27,120±1,789	71
PHA-P	50,346±5,157	37,345±2,734	74
PWM	17,956±912	13,033±733	73

[a] Statistical analysis was performed by Student's t-test. Mean cpm of normal donors' lymphocytes incubated in breast cancer sera ($n=14$) were compared to the mean cpm of normal donors' lymphocytes incubated in sera from normal individuals ($n=14$). The Con A, PHA-P, and PWM blastogenic responses were significantly decreased ($P<0.001$, <0.05, and <0.001, respectively) when cells were incubated in breast cancer sera as compared to cells preincubated in normal sera.

Normal donors' lymphocytes were preincubated in the presence of sera from breast cancer patients known to have elevated concentrations of OR or in the presence of sera from normal individuals and then tested for Con A receptor mobility. The total number of cells demonstrating ring, patch, and cap fluorescence is shown in table 2. The normal sera ($n=6$) used in these studies had a mean OR level ± SE of 0.70 mg/ml±0.04, whereas the breast cancer sera ($n=6$) had a mean OR level ± SE of 1.96 mg/ml±0.19. When normal donors' lymphocytes were preincubated in breast cancer sera, the total number of cells bearing ring fluorescence was significantly increased ($P<0.05$), and the total number of cells with caps was significantly decreased ($P<0.001$) as compared to normal donors' lymphocytes preincubated in normal donor sera. The number of cells showing patched fluorescence remained unchanged ($P>0.05$). These same sera were tested for their ability to support blast transformation in the presence of Con A, PHA-P, and PWM. Preincubation of lymphocytes from healthy donors in breast cancer sera resulted in a mean



TEXT-FIGURE 2.—Serum OR levels of metastatic breast cancer patients and normal donors. *Bars* represent mean OR concentration (mg/ml). Mean OR concentration in normal sera ($n=28$) is 0.77 mg/ml, and in breast cancer sera ($n=25$) it is 1.47 mg/ml. For experimental details, *see* "Materials and Methods."



TEXT-FIGURE 3.—Effect of OR concentration of breast cancer sera on the Con A-, PHA-P-, and PWM-induced (A, B, and C, respectively) blastogenic response of normal lymphoid cells. *Each point* represents the percent blastogenic response of normal lymphoid cells incubated in serum from a breast cancer patient as compared to those cells incubated in serum from a matched normal donor, as a function of the OR concentration (mg/ml) of each cancer serum tested. The *r* of Con A, PHA-P, and PWM responses are −0.70, −0.63, and −0.53, respectively. The effects of each serum tested were determined with lymphoid cells from 1 of 4 healthy donors. For additional experimental details, *see* "Materials and Methods."

TABLE 2.—*Con A ring, patch, and cap fluorescence in normal donors' lymphocytes incubated with normal or breast cancer sera*[a]

Flourescence type	Mean No. of fluorescent cells/200 cells ± SE after incubation with:	
	Normal sera	Breast cancer sera
Rings	131±4	146±5
Patches	34±2	35±4
Caps	34±2	19±2

[a] Statistical analysis was performed by Student's *t*-test. In each comparison, the number of fluorescent lymphocytes/200 lymphocytes preincubated in the presence of breast cancer sera was compared to the number of fluorescent lymphocytes/200 lymphocytes preincubated in normal sera. When lymphocytes were preincubated in breast cancer sera, the number of rings was significantly increased ($P<0.05$), and the number of caps significantly decreased ($P<0.001$).

blastogenic response of 56, 65, and 68% of the response in the presence of normal sera, respectively.

DISCUSSION

In the present study we demonstrated that sera from metastatic breast cancer patients are capable of inhibiting Con A-, PHA-P-, and PWM-induced activation of normal lymphoid cells. These reduced blastogenic responses were correlated with elevated OR levels in the sera of patients with metastatic breast cancer. OR is an acute-phase reactant, a component of normal serum that becomes elevated under conditions of acute inflammation, pregnancy, and neoplasia (*10*, *11*). This glycoprotein has been shown to be highly immunosuppressive when added to human lymphoid cells grown in vitro. OR was shown to inhibit mitogen-induced blast transformation, mixed lymphocyte responses, and T-cell rosette formation in the presence of sheep erythrocytes (*13*). A recent study in the murine system has shown that OR, when added to lymphocyte cultures, inhibits the induction of antibody-secreting cells and development of cell-mediated lympholysis against allogeneic target cells. Bennett and Schmid (*12*) implicated the carbohydrate portion of the molecule as being instrumental in its immunosuppressive capability

Experiments by Chiu et al. (*13*) demonstrated that human lymphocytes preincubated in OR and subsequently washed were inhibited in their capacity to be stimulated by mitogen. These investigators suggested that OR may inhibit lymphocyte activation by interacting with the cell surface. More recently, Gahmberg and Andersson (*16*) demonstrated that $F(ab)'_2$ anti-OR was able to bind to the membranes of lymphocytes, granulocytes, and monocytes. Work in our laboratory supports the concept that OR is capable of associating with membranes. We have shown that this glycoprotein interacts with synthetic phospholipid vesicles and is capable of displacing a membrane-bound anionic probe (Cheresh DA, Haynes DH, Distasio JA: Submitted for publication). Our results suggest that OR affects the net charge on the polar head region of the phospholipid membrane. Moreover, addition of pure OR to lymphoid cells in culture results in an inhibition of mitogen-induced activation as well as of receptor mobility. These experiments suggest that OR at elevated concentrations is capable of interacting with the lymphoid cell membrane and/or of modulating cellular mechanisms known to be associated with lymphocyte activation.

Receptor mobility as measured by Con A capping occurs in two stages. First, the ligand receptor complexes passively aggregate into multiple patches of variable size, and second, the patches aggregate into a single mass or a cap. Only the second stage is energy-dependent (*18*). The formation of patches is attributed to the ability of the ligand to cross-link receptors (*18*). Our results indicate that both stages in Con A receptor redistribution are affected, since we see a significantly greater number of cells with ring fluorescence in the breast cancer serum-treated lymphocytes as well as a significant decrease in the number of cells that demonstrate capped fluorescence. Therefore, it does not appear that normal lymphoid cells preincubated in breast cancer serum are simply metabolically inhibited, since ring-to-patch formation, which occurs spontaneously, is also inhibited.

Other studies have demonstrated that individuals known to have suppressed lymphoid function demonstrate reduced receptor capping. Markedly reduced Con A capping has been demonstrated as a function of age in humans (*19*). It is also well documented that lymphocytes from aged individuals respond poorly in mitogen-induced blastogenesis (*20, 21*). Similar findings have been reported in the aged rat, in which reduced receptor mobility of three lymphoid surface proteins was shown (*22*). Immune hyporesponsiveness was shown to correlate with age in these animals (*23*). An interesting note is that certain drugs that impede membrane receptor mobility are also very inhibitory to cell proliferation. Cytochalasin B, a drug known to perturb submembrane microfilaments, is inhibitory to cell proliferation (*24*) and has been shown to inhibit redistribution of membrane-bound ligands (*25*). Local anesthetics and tranquilizers have been shown to inhibit PHA-induced lymphocyte transformation (*26*) as well as inhibit membrane receptor redistribution (*27*). These agents prevent membrane depolarization (*28, 29*), which is a necessary step in lymphocyte activation and has been shown to occur within the first few minutes after mitogen binding (*30, 31*).

In this study we have demonstrated a correlation between the OR level and the inhibitory effects of breast cancer serum on mitogen-induced blastogenesis of normal lymphoid cells. Other serum components may play an immunosuppressive role. Previous studies have demonstrated various serum proteins known to be immunosuppressive, e.g., α-fetoprotein (*32*), C-reactive protein (*33*), and immunoregulatory α-globulin (*34*), are elevated in cancer patients. Elevation of any of these factors may affect the inhibitory capability of a patient's serum. However, in parallel work in which we added OR to normal human lymphocyte cultures, we were able to demonstrate a similar pattern of immunosuppression as that found with breast cancer serum containing elevated levels of OR. Therefore, OR must be considered as an additional serum protein that can influence lymphocyte responsiveness.

Zinc Deficiency, Alcohol, and a Retinoid: Association With Esophageal Cancer in Rats[1,2,3]

Gamal N. Gabrial,[4] Thomas F. Schrager,[4] and Paul M. Newberne[4,5]

ABSTRACT—Groups of Charles River Sprague-Dawley male rats were given intragastric intubations of methylbenzylnitrosamine after receiving one of the following diets for 4 weeks: control, zinc-deficient, or zinc-deficient diet plus 4% ethanol in the drinking water. One zinc-deficient group was zinc repleted after the dosing period; the other group, zinc-deficient plus 4% ethanol, received 13-*cis*-retinoic acid (13-*cis*-RA) after the dosing period. Zinc deficiency significantly enhanced esophageal tumor incidence; the addition of ethanol further enhanced tumor incidence. Zinc repletion reduced tumor incidence, whereas the addition of 13-*cis*-RA enhanced tumor incidence.—JNCI 1982; 68:785–789.

A previous study in this laboratory showed that zinc deficiency (7 ppm in the diet) enhanced the incidence and reduced the lag time for the induction of esophageal tumors in rats by MBN (*1*). A more recent study showed that chronic alcohol consumption also had an enhancing effect on MBN esophageal carcinogenesis (*2*). These results are consistent with epidemiologic findings that link both of these factors to increased risk of the disease in certain parts of the world (*3–6*). Nevertheless, neither of these factors is consistently linked to the disease worldwide, which suggests that more complex interactions of additional factors may be involved in the etiology of this neoplasm.

This study was undertaken to further examine the effects of zinc deficiency on MBN-induced esophageal carcinogenesis alone and in combination with chronic alcohol consumption. In addition, we examined the effects of the synthetic retinoid 13-*cis*-RA on the tumor growth phase of animals exposed to both zinc deficiency and chronic alcohol consumption. To more closely pinpoint the effects of zinc deficiency on the MBN carcinogenic process, we repleted one deficient group with zinc after the carcinogen-dosing period to separate the effects exerted by zinc deficiency during the initiation period from those exerted over the entire course of carcinogenesis.

MATERIALS AND METHODS

Experimental animals.—Weanling male outbred Sprague-Dawley rats (Charles River Breeding Laboratories, Wilmington, Mass.) were housed in plastic cages as described previously (*1*). After an appropriate adjustment period, they were started on the diet listed in table 1. The protein source was C-1 assay protein isolated from soybean (The Skidmore Co., Cincinnati, Ohio). We reduced the zinc content of the soybean protein isolate by washing the isolate several times with a solution of the tetrasodium salt of EDTA (pH 4.3). The basal zinc-free diet, mixed in our laboratory, contained about 2 ppm zinc. After zinc carbonate was added, the control diet contained 60 ppm of zinc and the zinc-deficient diet contained 7 ppm. All animals were fed ad libitum. They were given free access to either deionized water or deionized water containing 4% ethanol. After the rats had been on their respective diets for 4 weeks, MBN was administered intragastrically, at the rate of 2 mg/kg body weight, twice weekly for 4 weeks. One group of rats receiving control diet received no MBN. At the end of the MBN-dosing period, one zinc-deficient group was switched to control diet (zinc repletion; group 4), and another group receiving zinc-deficient diet plus 4% alcohol was provided a dietary supplement of 67 µg 13-*cis*-RA/g diet (group 6). These dietary regimens were maintained for 29 weeks until the termination of the experiment. At this point all animals were killed and complete autopsies were performed. The number and distribution of animals are shown in table 2. All animals were weighed weekly; growth rates are shown in text-figure 1.

Hair.—Hair was sheared with an electric clipper from the dorsal skin over the point of the shoulders at the start of the experiment, immediately before MBN dosing and 1 month after the end of MBN dosing. Hair samples (≈30 mg) were analyzed for zinc and copper contents according to the methods of Kopito (*7*) and McBean et al. (*8*).

Blood.—Blood samples were taken by orbital puncture at the beginning of the study, immediately before carcinogen dosing, at the end of the carcinogen-dosing period, and 1 month after the end of dosing. All containers and glassware used were cleaned with nitric acid. Serum copper and zinc were determined by direct aspiration of 1:8 dilutions of serum in deionized water into the atomic absorption spectrophotometer (*9*).

Microsomal enzyme assays.—At the end of the study, liver samples from selected animals in each group were assayed for activity of two microsomal enzymes, PNA and aryl hydrocarbon hydroxylase, according to procedures standard to this laboratory (*10*).

RESULTS

Serum zinc and copper levels.—Serum zinc and copper levels

ABBREVIATIONS USED: 13-*cis*-RA=13-*cis*-retinoic acid; MBN=methylbenzylnitrosamine; PNA=*p*-nitroanisoledemethylase.

remained stable throughout the experiment in the 2 control diet groups (with or without MBN) (table 3). There was a significant drop in serum zinc levels after 1 month on the zinc-deficient diet for groups 3–6. These levels remained low except in the zinc-repleted group (group 4) in which zinc levels returned to normal within 1 month after repletion. Alcohol consumption or 13-*cis*-RA had no effect on serum zinc levels beyond that exerted by the zinc deficiency.

Copper levels approached a significant increase (P=0.05) in the zinc-deficient group after 1 month. Copper serum levels increased significantly after 3 months in the zinc-deficient plus alcohol group and after 2 months in the zinc-deficient plus alcohol plus 13-*cis*-RA group.

Hair zinc and copper levels.—Hair zinc levels remained constant in both control diet groups, with or without MBN (table 4). In the 4 zinc-deficient groups, zinc levels dropped significantly after 1 month. Zinc levels in the repletion group (group 4) remained low 1 month after repletion. Copper levels remained constant throughout the experiment in all groups.

Body weight.—There was no significant difference between the 2 control diet groups with or without MBN (text-fig. 1). The weights of the zinc-deficient groups decreased significantly during weeks 3 and 4. This was also the time at which other symptoms of zinc deficiency began to appear, such as alopecia, coarse fur, and dermatitis. The zinc-deficient plus alcohol group (group 5) weighed less than the zinc-deficient group; addition of 13-*cis*-RA had no effect on growth. Upon repletion with zinc, group 4 quickly began to gain weight approaching that of the controls.

Microsomal enzyme activity.—There was little variation in PNA activity among the various groups except for a slight increase (on a milligram per microsomal protein basis) in the zinc-deficient group receiving MBN, alcohol, and 13-*cis*-RA. The zinc-deficient group that was returned to control diet after MBN treatment (group 4) had the highest total liver PNA activity.

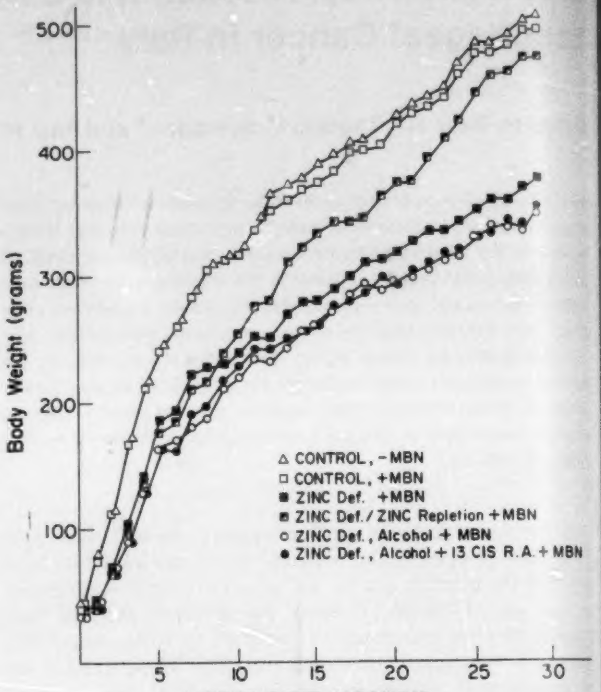
Tumorigenesis studies.—Zinc deficiency significantly enhanced MBN-induced esophageal tumor incidence as com-

TABLE 1.—*Composition of the basal zinc-free diet*

Component	Amount fed, g/100 g
Soybean protein	30.0
Methionine	0.7
Corn starch	26.5
Sucrose	27.0
Cellulose fiber	5.0
Mazola corn oil	5.0
Mineral mix[a]	3.5
Vitamin mix[b]	2.0
Choline chloride	0.3
Vitamin B_{12} (μg)	5.0

[a] Composition of mineral mix in grams: $CaCO_3$, 190.5; $CaHPO_4$, 144.1; K_2HPO, 403.8; $MgCO_3$, 73.2; $MgSO_4 \cdot 7H_2O$, 191.7; $FeSO_4 \cdot 7H_2O$, 17.4; $MnSO_4 \cdot H_2O$, 15.4; KI, 0.02; $CuSO_4 \cdot 5H_2O$, 1.96; NaF, 0.22; NaCl, 82.4; $NaCO_3$, 40.6; $Cu_2(SO_4) \cdot H_2O$, 0.009; $NaSeO_3$, 0.02; glucose, 1,041.

[b] Composition of vitamin mix in grams: menadione, 0.1; riboflavine, 0.4; thiamine HCl, 0.8; pyridoxine, 0.8; calcium pantothenate, 2; folic acid, 1; nicotinic acid, 5; inositol, 25; Roche A & D mix (500/50), 6; *dl*-α-tocopherol acetate (500 U/g), 22.5; [illegible] 1,941.



TEXT-FIGURE 1.—Growth curves of different dietary groups. Weights of zinc-deficient groups are significantly less (P<0.001) than those of controls after 3 wk. Weight of zinc-deficient, zinc-repleted group is no longer significantly less than weights of controls after 15 wk.

TABLE 2.—*Animal groups, treatment, and tumor incidence*[a]

Group No.	Total No. of rats	Dietary zinc, ppm	MBN[b]	4% ethyl alcohol in drinking water	13-*cis*-RA[c]	No. of rats with tumors/ No. of survivors (%)	Total No. of tumors	Average No. of tumors per rat

pared with that among rats on control diet (75.7 vs. 40%, $P<0.005$). The addition of alcohol to the zinc-deficient diet (group 5) further enhanced tumor incidence (85.3%), although this increase was not statistically significant ($P=0.05$). Addition of 13-*cis*-RA to the diet (group 6) at the end of carcinogen treatment enhanced tumor incidence even further. Again, this enhancement was not significantly different ($P=0.05$) from the tumor level produced by zinc-deficient diet alone. Morphologically, tumors in the 13-*cis*-RA group tended to coalesce, which made counting of the individual tumors difficult. When a zinc-deficient dietary group was switched to a control diet (group 4) after the end of carcinogen treatment and was continued on control diet for 21 weeks until the end of the experiment, at week 29, a significantly reduced tumor incidence from the level of the zinc-deficient group was observed (75.7 vs. 51%, $P<0.05$).

DISCUSSION

The dramatic fluctuations in esophageal cancer incidence from one geographic area of the world to another provide a unique opportunity to identify factors associated with increased risk of the disease and to test these factors experimentally. Although this epidemiologic approach has linked a number of environmental agents to the risk of this neoplasm, none of the factors shows a consistent association to increased worldwide esophageal cancer mortality (*11*). Therefore, more complex interactions of a number of factors may impinge on the etiology of esophageal cancer.

As shown in table 2, additional factors can modify the enhancing effects of zinc deficiency on MBN esophageal carcinogenesis. Zinc deficiency alone (group 3) significantly enhanced tumor incidence, comparable to what was found in an earlier study (*1*) (75.7% in zinc-deficient group vs. 40% in the control diet group, compared to 79% in the zinc-deficient group vs. 29% in the control diet group in the previous study). This similarity is noteworthy since in the previous study animals on control diet were pair-fed to zinc-deficient animals, whereas in this study all groups received food ad libitum. Pair-feeding was used in the earlier study to document the effects of zinc independently of food intake and reduced growth. As shown in text-figure 1, zinc-deficient animals experienced a reduced growth rate compared to that in rats receiving control diet ad libitum. Reduced growth rate is accompanied by a reduction in food intake.

Comparison of these studies suggests that what little effect, if any, results from reduced food intake and reduced growth is a reduction in tumor incidence. This observation has been substantiated in a more recent study (Schrager TF, Newberne PM: Unpublished data) and is consistent with the hypothesis that reduced calorie intake may reduce tumor production. These findings confirm that the enhancement of tumor incidence resulting from a zinc-deficient diet is not due to the reduction in growth rate; on the contrary, this reduction might understate slightly the significance of the effect of zinc deficiency on tumor incidence.

Although it has not been established that defects in the immune system can enhance carcinogenesis, this possibility exists and the role of zinc in the immune system should be considered. Zinc deficiency causes atrophy of lymphoid tissues and can lead to derangements in both humoral and cellular immunity (*12*, *13*). This relationship requires further investigation.

To determine more clearly the effect of zinc deficiency on the initiation phase of carcinogenesis, we placed group 4 rats on a zinc-deficient diet before and during carcinogen treatment and then returned them to a control (zinc-sufficient) diet for the remaining 21 weeks of the experiment. This protocol would also indirectly indicate the effects of zinc deficiency on the tumor growth phase. The tumor growth effect was of interest in light of previous findings by McQuitty et al. (*14*), Duncan and co-workers (*15*), and DeWys and Pories (*16*) that zinc deficiency can inhibit the growth of a variety of tumors. If this were the case in the MBN–esophageal tumor model, it would mean that zinc deficiency enhancement must occur during the initiation phase. Therefore, if we eliminated the deficiency during tumor growth, maximum tumor production would occur. Instead of maximum tumor production, we observed the opposite effect. Zinc repletion reduced tumor incidence to a level approaching that in animals receiving control diet throughout the experiment (51% tumors on zinc repletion vs. 40% on control diet). This finding suggests that zinc deficiency during the tumor growth phase of MBN-induced esophageal cancer, rather than inhibiting tumor growth, provides a major enhancement to tumor incidence, as evidenced by comparison of the zinc-repleted rats (group 4) with the rats (group 2) that received zinc-deficient diet during both initiation and promotion (51 vs. 75.7%, respectively). Whether this effect of zinc deficiency during tumor growth occurs only in combination with zinc deficiency during tumor initiation or would occur if applied during tumor growth alone has not been determined and requires further study.

The enhancement of esophageal tumor growth by zinc deficiency, in contrast to an inhibition of tumor growth in other tissues that have been studied, parallels the difference in the generalized response to zinc deficiency of esophageal epithelium compared to other tissues. This finding suggests a possible mechanism by which zinc deficiency might enhance esophageal tumor incidence. Whereas most other tissues exhibit a hypoplastic response to zinc deficiency and show tumor inhibition, the esophageal epithelium exhibits a hyperplasia and parakeratosis (*17–20*), conditions that might enhance the susceptibility of this tissue to initiation by chemical carcinogenesis and promote the subsequent growth of tumors (*21*, *22*).

The addition of chronic alcohol consumption to the zinc-deficient diet (group 5) further enhanced tumor incidence (85.3 vs. 75.7%). Although this level was not significantly different from the tumor level in the zinc-deficient group, this degree of enhancement has been observed in two other experiments, indicating a consistent trend. Whether alcohol exerts an effect on MBN carcinogenesis through a pathway similar to the pathway of zinc deficiency has not been determined. There are a number of possible mechanisms for the action of alcohol. Karatsume and co-workers (*23*) found that among a number of solvents, ethanol was most effective in enhancing the penetration of benzo[*a*]pyrene and other polycyclic hydrocarbons into the esophageal mucosa. Furthermore, alcohol can alter the activity of mixed function oxidases (*24*, *25*), a group of enzymes involved in the metabolism of most carcinogens, including nitrosamines. An alteration in the activity of these enzymes could affect the ultimate amount of carcinogens produced. In addition, a prolonged exposure to ethanol can dehydrate and irritate such tissues as the esophageal epithelium (*8*) and cause esophagitis and other disturbances in the integrity of this protective barrier, such as hyperplasia (*11*) and other conditions that might enhance susceptibility of the esophageal epithelium to chemical carcinogens. Another possibility is that chronic alcohol consumption causes nutritional deficiencies or imbalances, either by replacing nutrient-rich calories of food with nutrient-free calories of alcohol, or by increasing the excretion of nutrients from the body. These nutritional disturbances may then alter the organism's response to carcinogenic exposure (*11*). Studies by Vallee and co-workers (*26*) showed that cirrhotic alcoholics had reduced serum zinc levels and hyperzincuria. Sullivan and Lankford (*27*) found increased zincuria in 50% of noncirrhotic alcoholics. Flynn and co-workers (*28*) found significantly lower plasma zinc levels in alcoholic pregnant women than in nonalcoholic pregnant women. Wang and Pierson (*29*) found that plasma zinc levels dropped significantly after 14 weeks in rats consuming 20% alcohol. If such an effect of alcohol on zinc status does exist, it suggests a connection between these two factors in the etiology of esophageal cancer.

The addition of 13-*cis*-RA to the zinc-deficient diet plus ethanol group (group 6) during the tumor growth period further enhanced tumor incidence. Although the level of enhancement in this group was not statistically significant compared to that in the zinc-deficient diet plus alcohol group, this same effect has been observed in an additional study (the results of which are in preparation or in press) and indicates a trend. On the basis of studies in our laboratory showing a protective effect of 13-*cis*-RA on bladder tumor incidence (Newberne PM: Unpublished observation) and other studies showing similar effects (*30*), this enhancement is somewhat unexpected. Whether this enhancement is specific to MBN esophageal carcinogenesis or is the result of an interaction between the synthetic retinoid and zinc deficiency and/or chronic alcohol consumption is unclear and requires further investigation.

Oral Mucosal Carcinogenesis in Hamsters: nhibition by Vitamin E[1,2]

Gerald Shklar, *D.D.S., M.S.*[3]

ABSTRACT—Eighty young adult male and female Syrian golden hamsters (*Mesocricetus auratus*) were divided into 4 equal experimental groups. In group 1 animals the left buccal pouch was painted three times weekly with a 0.5% solution of 7,12-dimethylbenz[*a*]anthracene DMBA) in heavy mineral oil. In group 2 animals the left buccal pouch was similarly painted with DMBA, but the animals also received orally 0 mg vitamin E (*dl*-α-tocopherol) in peanut oil twice weekly on alternate days with the DMBA painting. Group 1 animals received a similar amount of peanut oil vehicle, group 3 animals received only vitamin E vitamin E controls) in peanut oil, and group 4 animals served as untreated controls receiving only peanut oil. Four animals in each group (2 males and 2 females) were killed at 8, 10, 12, 14, and 16 weeks. Buccal pouches were photographed and excised, and tumors were noted and measured in the left buccal pouches. In group 2 animals receiving vitamin E, tumor formation was significantly delayed, so that by 14-16 weeks there were fewer tumors and their average size was smaller than that of tumors in group 1 animals that were painted with DMBA but received no vitamin E supplement. In group 2 there was also less invasion of underlying tissues and less surface necrosis.—JNCI 1982; 68:791-797.

There has been renewed interest recently in nutritional supplements as cancer chemopreventive agents (*1*). Inhibition of tumor growth by retinoids has been reported in a variety of experimental tumor systems, including carcinomas of the bladder (*2, 3*), skin (*4*), lung (*5*), and breast (*6*). Recently, these findings were confirmed in two oral mucosal tumor systems: 1) the hamster buccal pouch painted with DMBA in oil (*7*) and 2) the hamster tongue painted with DMBA in acetone (*8, 9*). Vitamin E (α-tocopherol) has received some renewed interest in recent years and has been accepted as an essential nutrient for humans (*10*), although its physiologic role has not been significantly clarified and its relation to pathologic states remains controversial. A major function of vitamin E in animals appears to be that of an antioxidant, inhibiting both enzymatic and nonenzymatic lipid peroxidation and preventing the spread of peroxidation through lipids, perhaps in membranes (*11-14*).

The relationship of vitamin E to experimental tumors had been reported in early studies with contradictory results. Davidson (*15*) in 1934 found a delay in skin carcinogenesis in mice on a diet high in vitamin E. Telford (*16*) in 1949 found that vitamin E supplements increased the percentage of lung tumors in a tumor strain of mouse and that vitamin E deficiency resulted in decreased numbers of tumors.

More recently, Harman (*17*) reported that dietary vitamin E inhibited dibenzanthracene-induced tumors. Slaga and Bracken (*18*) found that vitamin E and other antioxidants were effective inhibitors of DMBA-induced tumor initiation and attributed their activity to their ability to prevent the in vivo activation of polycyclic aromatic hydrocarbons to carcinogen epoxides or other intermediates. Cook and McNamara (*19*) found that mice receiving a diet with a high vitamin E content developed fewer adenomas and fewer invasive carcinomas of the colon than mice receiving dimethylhydrazine and a normal diet.

The hamster buccal pouch tumor system is an excellent model for oral epidermoid carcinoma and has been shown in numerous studies to be a reliable experimental system, with consistent time patterns of tumor development as well as the preceding precancerous leukoplakic lesions (*20*). Dysplastic leukoplakic lesions develop at 6-8 weeks, carcinoma in situ at 8-10 weeks, frank epidermoid carcinomas at 10-12 weeks, and large verrucous and invasive carcinomas at 12-14 weeks. It was decided that a study of the effect of vitamin E on hamster buccal pouch carcinogenesis could effectively confirm some of the recent reports on the role of vitamin E as a possible tumor inhibitor.

A chemical carcinogenesis system such as the hamster buccal pouch offers a more reliable indication of tumor retardation or prevention than do systems that use transplanted tumors. The oral chemical carcinogenesis system more closely approximates the human cancer situation, with a relatively long latent period, slow growth, carcinoma rather than sarcoma development, noninbred host, and the presence of viruses uncommon. In contrast, transplantation models use inbred hosts, the tumors are predominantly sarcomas or leukemia in an advanced stage of progression with no latent period, the tumors grow rapidly, and passenger viruses are common (*21*). Furthermore, there are no spontaneously arising tumors of the hamster buccal pouch that could complicate the interpretation of tumor development stimulated by the chemical carcinogen.

MATERIALS AND METHODS

Eighty young adult male and female noninbred Syrian golden hamsters (*Mesocricetus auratus*) 4-6 weeks of age served as experimental animals. They were obtained from Charles River Breeding Laboratories, Wilmington, Mass. The animals were housed 5 per plastic cage with wood chips for bedding. The environment was controlled with an alternating 12-hour light-dark cycle. Water and laboratory chow (Rat Chow 5012; Ralston Purina Co., St. Louis, Mo.) were

available ad libitum. The hamsters were divided into 4 equal groups of 20 (10 males and 10 females) and were treated as follows: group 1—DMBA painted; group 2—DMBA painted and vitamin E administered; group 3—vitamin E administered; and group 4—untreated controls.

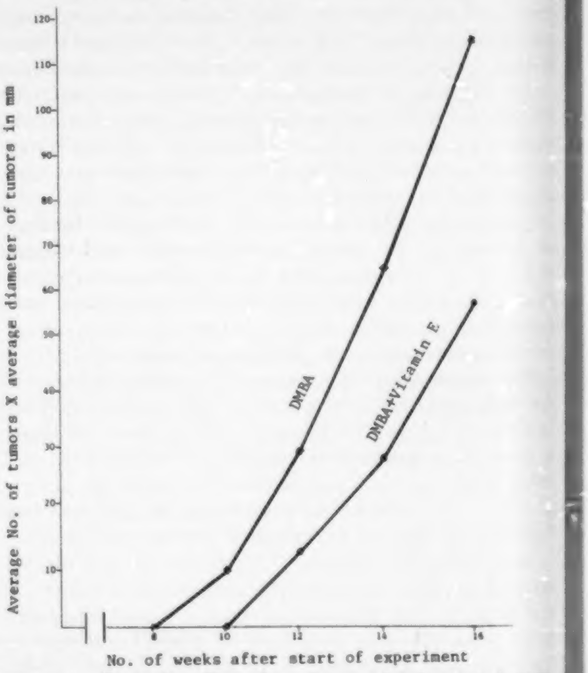
DMBA (Sigma Chemical Co., St. Louis, Mo.) in a 0.5% solution in heavy mineral oil (U.S.P.) was painted on the left buccal pouch mucosa three times per week. Vitamin E (DL-α-tocopherol; Sigma Chemical Co.) was dissolved in peanut oil and administered by mouth with a thin pipette twice weekly in a dose of 10 mg (4 drops of a 50-mg vitamin E solution/ml). Vitamin E was offered on alternate days with the DMBA painting. Both group 1 animals (DMBA) and group 4 animals (untreated controls) received 4 drops of peanut oil on a schedule similar to that of vitamin E to control for the vitamin E vehicle.

Two male and 2 female animals in each group were killed at 8, 10, 12, 14, and 16 weeks after the initiation of the experiment. Buccal pouches were photographed, dissected, fixed in 10% Formalin, sectioned in paraffin, and stained with H & E for microscopic study. Major organs (liver, kidneys, spleen, heart, and lungs) were also removed at autopsy, fixed in 10% Formalin, and prepared for microscopic evaluation. Grossly observed buccal pouch tumors were counted, and the figures were used for statistical analysis. Student's *t*-test for paired data was used to determine level of significance. Diameters of tumors were also measured.

RESULTS

Gross observations.—Both the appearance of leukoplakia and the development of visible tumors in the left pouches of the group 2 animals (DMBA + vitamin E) were significantly delayed as compared to those seen in group 1 animals (DMBA) (table 1, text-fig. 1). Tumors at all stages of development in group 2 animals tended to be smaller than those in group 1 animals and their numbers were fewer (figs. 1-6). No abnormalities were noted in group 3 and group 4 control animals. No significant changes were observed in liver, kidneys, spleen, heart, and lungs at autopsy in animals in any of the 4 groups. Two animals in group 1 with extensive large tumors of the left buccal pouch mucosa at 16 weeks appeared to have some tumor extension into the cervical region, with fixation of the buccal pouch to the underlying tissue.

Statistical analysis.—In each of the 4 groups studied, 4 animals were randomly killed at 8, 10, 12, 14, and 16 weeks after the start of the experiment. Determination of statistical results was based on the gross observation of the number of tumors in the left buccal pouches of animals killed from 8 to 16 weeks in each of the 2 groups. The mean and standard deviation were calculated for each group. Student's *t*-test for paired data was used to determine the level of statistical significance between groups, and the *P*-values are indicated. The mean value and standard deviation for group 1 were 32±18.7, and the values for group 2 were 19±14.0. There was a statistically significant difference ($P \leq 0.01$) in tumor numbers between groups 1 and 2.



TEXT-FIGURE 1.—Expression of buccal pouch tumor involvement. Average tumor number and size in animals from group 1 (DMBA) and group 2 (DMBA+vitamin E) from 8 and 10 wk, respectively.

Microscopic observations.—In group 1 animals the left buccal pouches demonstrated hyperkeratosis and dysplasia at 8 weeks, areas of carcinoma in situ and small papillary carcinomas at 10 weeks, larger papillary and invasive carcinomas at 12 weeks, and more extensive lesions at 14 weeks with extensive inflammatory infiltrate beneath the carcinomas and surface necrosis. At 16 weeks the large carcinomas were often confluent, and there were extensive surface necrosis and deep invasion into underlying tissues.

In group 2 animals, the left buccal pouches demonstrated similar pathology, but with a delay in development of lesions, so that buccal pouch mucosa appeared relatively free of dysplastic changes at 8 weeks, although some hyperkeratosis was observed as well as lymphocytic infiltration of underlying corium (figs. 7, 8).

At 16 weeks, there were fewer tumors, individual tumors tended to be smaller than those in the group 1 animals, and there was less surface necrosis. Less evidence was observed of deep extension into underlying tissue (figs. 9, 10).

DISCUSSION

The experimental results confirm previous preliminary findings in other experimental tumor systems that vitamin E is capable of delaying tumor formation or retarding carcinogenesis. The hamster buccal pouch model offers reliable data on tumor development, and the tumors can be observed, studied, and measured at various stages. The observations are somewhat comparable to those with retinoids and with immunoenhancing agents (*22*) such as bacillus Calmette-Guerin (*23*) and levamisole (*24*). There is some suggestion that retinoids may also retard carcinogenesis by serving to enhance the organism's immune response, since stimulation of cell-mediated immunity by retinoids has been demonstrated in both mice (*25*) and hamsters (*26*). Perhaps vitamin E functions in a similar manner, although antioxidant action suggests a more obvious role in delaying chemical carcinogenesis by preventing the formation of proximal carcinogens, now considered to be the diol epoxides (*27*).

Another possible role could relate to the finding that vitamin E has a stimulatory effect on the microsomal hydroxylation of drugs in livers of experimental rats. Since liver microsomes catalyze the hydroxylation of carcinogenic hydrocarbons, this might in some way also inhibit the development of proximal carcinogens (*28*).

The minimum nutritional requirement of α-tocopherol for adult humans appears to be in the range of 5–7 mg/day, and the average intake in the United States is 7–9 mg/day (*29*). Recommended dietary allowance is currently 8–10 mg/day.

Vitamin E is adequately absorbed in the gastrointestinal tract so that it can be administered orally (*30*).

Thy-1 Antigen on Normal and Neoplastic Rat Mammary Tissues: Changes in Location and Amount of Antigen During Differentiation of Cultured Stem Cells[1,2]

Philip S. Rudland,[3] Michael J. Warburton,[3] Paul Monaghan,[3] *and* **Mary A. Ritter[4,5]**

ABSTRACT—With the use of immunofluorescent and immunocytochemical techniques on histologic sections of mammary glands from inbred WF rats, the thymocyte differentiation antigen (Thy-1) was identified partially on and immediately adjacent to the myoepithelial cells of ducts and alveoli. This antigen was absent from epithelial cells lining such structures. Some fibroblastic cells external to these structures also bore Thy-1. During glandular development the intensity of fluorescence due to the binding of Thy-1 antibodies increased as the myoepithelial cells matured. Similarly, mammary adenocarcinomas induced by 7,12-dimethylbenz[*a*]anthracene (DMBA) and *N*-methyl-*N*-nitrosourea contained elongated, presumptive myoepithelial cells that demonstrated varying degrees of Thy-1 immunofluorescence. This phenomenon was qualitatively mimicked by cultured cell lines from normal and DMBA-induced tumors. Elongated myoepithelial-like and fibroblast-like cells possessed Thy-1, whereas the cuboidal epithelial cell lines failed to express this antigen on the cell surface. Measurement of the relative number of Thy-1 molecules per cell by antiserum absorption techniques suggested that a neoplastic stem cell line, rat mammary (Rama) 25, contained about 3×10^5 Thy-1 molecules per cell in a form not directly accessible at the cell surface to anti-Thy-1 antibodies; the number of cryptic Thy-1 molecules was reduced when this cell line differentiated to alveolar-like cells in culture. However, when this cell line differentiated to myoepithelial-like cells, approximately 5×10^6 molecules per cell were exposed to anti-Thy-1 antibodies with a concomitant reduction of the cryptic pool. Morphologic maturation of elongated, myoepithelial-like cell line variants was also accompanied by increased surface Thy-1 fluorescence. Thus some of the myoepithelial cells in normal glands and tumors may arise by differentiation of epithelial stem cells and a spectrum of maturation states of the myoepithelial cell may exist as monitored by cellular morphology and surface Thy-1 expression.—JNCI 1982; 68:799–811.

The epithelial component of an adult female rat mammary gland consists of two structures, ducts and alveoli. Each structure contains a central lumen surrounded by lining epithelial cells, which are in turn surrounded by elongated, contractile myoepithelial cells. The cells lining the alveoli secrete milk-specific products during pregnancy and lactation (*1*). Recent in vitro (*2*) and in vivo (*3*) studies have raised the possibility that mammary epithelial development can take place by processes similar to those encountered in the hematopoietic system (*4–6*). In hematopoiesis all blood cells are formed by cell proliferation and differentiation from a population of pluripotent stem cells, whereas in the mammary system an epithelial stem cell line (Rama 25) has been cloned from an adenocarcinoma that can proliferate and differentiate to form the other two major epithelial cell classes: alveolar-like and myoepithelial-like cells. The cell surface differentiation antigen Thy-1 has been of considerable use as a marker in mapping hematopoietic development in the rat (*7–11*), and recent experiments suggest that Thy-1 may act as an adhesive molecule involved in cell positioning and migration (*12, 13*). Since Thy-1 is also present on mouse mammary tissue (*14*) and some rat mammary cell lines (*15*), this molecule may also be important in rat mammary differentiation. We now report on the appearance of Thy-1 during normal and neoplastic rat mammary development in vivo and in cloned cell lines in vitro. This work establishes the validity of Thy-1 in cloned cell lines in vitro as an experimental system for the investigation of the role of Thy-1 in mammary cell differentiation and has enabled us to make quantitative studies of both cryptic and cell surface Thy-1 in mammary stem and myoepithelial cells, respectively.

MATERIALS AND METHODS

Source and preparation of tissue and tumors.—ICRF inbred WF rats were used. We induced tumors in 50-day-old females by feeding them either 20 mg DMBA/100 g in corn oil (15 mg/ml) by a stomach tube (*16*) or by giving them two injections iv (separated by a month) of 5 mg MNU/100 g in 20 mg Earle's salts/ml (pH 6.0) (*17*); tumors developed within 2 or 3 months, respectively, and more than 90% were mammary adenocarcinomas (*18*). Sarcomas were produced by sc injection of 10^6 polyomavirus-transformed rat fibroblasts and harvested after 1 month. All tumors were excised at about 1 cm in diameter before they became necrotic. For normal tissues, female rats of varying ages were killed and the lower pairs of mammary glands routinely removed. The other mammary glands gave essentially the same histologic

Neville (Ludwig Institute for Cancer Research) for valuable advice.

appearance. All tumors and tissues were cut into slices, which were then fixed in 5% glacial acetic acid–95% absolute ethanol (4°C), embedded in polyester wax (37°C), sectioned at 2½ and 5 μm, and stored at 4°C (*19*). For immunocytochemical localization of myosin and type IV collagen, pieces from parallel glands were fixed for 1 day in Methacarn (10% acetic acid, 30% chloroform, and 60% methanol) before being embedded in paraffin wax and sectioned.

Isolation and growth of cell lines.—The isolation of the rat mammary cloned cell lines Rama 25, Rama 27, and Rama 29 has been described previously (*2–4*). These and the remaining lines used are documented in table 1. The new cuboidal clonal cell lines Rama 41 (*20*), Rama 75, and Rama 102 from normal rudimentary glands of 7-day-old female ICRF WF rats were obtained from primary cultures of mammary epithelial cells (*21*) growing in Ham's nutrient mixture F-12 that had been exposed for 1 day to confluent cultures of Rama 29 (CM) and that had been reinforced with 10–30 ng epidermal growth factor/ml, 50 ng hydrocortisone/ml, 50 ng insulin/ml, and 10% FCS. Cell transfers, removal of contaminating fibroblasts, and single cell cloning procedures were performed as described previously (*2*). The single cell cloned lines Rama 29T and Rama 259 are variants of Rama 29 and Rama 25, respectively, selected independently for crisscross morphology and high proliferation rates and ability to grow in medium containing 1.8% DMSO. Rama 300 was obtained by single cell cloning of the fast-sticking cell fraction (*21*) of a DMBA-induced mammary carcinoma. Rama 500, Rama 502, and Rama 503 were single cell clones of "floaters" obtained when medium containing confluent cultures of Rama 25 cells was replated (*5*). Cell lines were all grown in DMEM, 10% FCS, 50 ng hydrocortisone/ml, and 50 ng insulin/ml, except the following lines: Rama 41 (DMEM was replaced by 100% CM) and Rama 75 and Rama 102 (DMEM was replaced by 50% CM and 50% DMEM). All cells were maintained at 37°C in 10% CO_2 in air. We obtained cuboidal cell cultures of Rama 25, Rama 41, Rama 75, Rama 102, and Rama 259 by harvesting subconfluent ($\approx 1.5 \times 10^6$ cells/9-cm dish) cultures between fixed passage numbers (e.g., for Rama 25 cells; only those between passage 25 and 28 were used), the dilution factor on each passage being 8. "Droplet" and "doming" (*22*) cultures were obtained by the following procedure: Rama 25 and Rama 75 cells were plated at 2×10^5 cells per 9-cm dish and grown to confluence for 5 days in DMEM, 10% FCS, 50 ng hydrocortisone/ml, and 50 ng insulin/ml. The medium was then replaced by a similar medium containing 500 ng prolactin/ml, and a further change to medium containing 250 m*M* DMSO was made 2 days later. All cultures were harvested after 2 days' exposure to DMSO. These cultures were considered to contain alveolar-like cells (*3, 23*). Rama 259 did not form domes under these conditions. Lump structures (*5*) that inhibited dome formation occurred in high-passaged (passage 29 or 30) cultures of Rama 25 and Rama 75 (passages 15 and 16). Cultures in which both structures were required were used at passage 28 or 29 (Rama 25) or passage 14 or 15 (Rama 75), and cultures in which only droplet cells and domes were required were used at passage numbers below these. Cultures for immunofluorescence were grown on plastic cover slips (*2*), washed twice with PBS, and then fixed, usually for 2 hours in 95% ethanol at 4°C. Although mammary epithelial cells did not grow well on glass cover slips, these were required when acetone alone was used as a fixative. After 2 hours the cover slips were transferred to 70% ethanol at 4°C before use, preferably on the same day.

Antisera.—Four anti-Thy-1 antisera were used in each experiment reported. The first antiserum, from Dr. R. J. Morris, was an F(ab')$_2$ preparation of a rabbit antiserum to pure rat brain Thy-1. It contained three known specificities: Thy-1.1 alloantigen, 8%; rat–mouse cross-reacting Thy-1 xenoantigen, 41%; and rat-specific Thy-1 xenoantigen, 51%

[a] Cells were scored for fluorescence intensity on a scale from zero (−) to maximum (++++) from four fields from four cover slips and the mean was recorded.

[b] On the basis of electron microscopic and biochemical evidence (*3, 5*).

[c] On the basis of light microscopic evidence only, and similarity in behavior to characterized cells.

(*24*). It was either conjugated directly to FITC (ratio of *F*-value to *P*-value=1.7) or used in the indirect immunofluorescence assay with $F(ab')_2$–sheep anti-rabbit $F(ab')_2$–FITC or goat anti-rabbit immunoglobulin–FITC as the second antibody. The second antiserum from Dr. A. F. Williams was the $F(ab')_2$ preparation of a monoclonal anti-Thy 1.1 antiserum (*25*). The two alloantisera anti-Thy 1.1 (C3H anti-AKR) and anti-Thy 1.2 (AKR anti-C3H) were purchased from Nordic Immunological Laboratories. All three mouse antisera were used in combination with FITC-labeled goat anti-mouse immunoglobulin (Nordic Immunological Laboratories). Pure rat brain Thy-1, antisera to myosin, and type IV collagen were kindly given by Dr. R. J. Morris, Dr. M. J. Owen (*26*), and Dr. L. A. Liotta (*27*), respectively.

Immunofluorescence and immunocytochemistry.—Tissue sections were dewaxed (*19*), followed by two 10-minute washes in isotonic PBS. Cultured cells on cover slips were rinsed twice with PBS. Specimens were then incubated for 30 minutes at room temperature with 10–20 μl of the following concentrations of antisera: 75 μg FITC-labeled $F(ab')_2$ rabbit anti-rat Thy-1/ml, 37 μg unconjugated rabbit anti-rat Thy-1/ml, 10 μg monoclonal anti-Thy 1.1/ml, and 1:5 dilutions of anti-Thy 1.1 and anti-Thy 1.2 alloantisera. Specimens were then rinsed for 20 minutes two times in PBS, and those not exposed to the FITC-conjugated antiserum were further incubated for 30 minutes with 10–20 μl of either FITC–sheep anti-rabbit $F(ab')_2$ (60 μg/ml) or FITC–goat anti-rabbit immunoglobulin (1:10) or FITC–goat anti-mouse immunoglobulin (1:5) as appropriate, followed by further 20-minute washes (two times) with PBS. Tissues were mounted in PBS–glycerol (9:1) (pH 8.2). Fluorescence was examined with a Zeiss RA microscope equipped with epi-illumination optics. Photography was done on Ilford HP5 film with the use of an exposure time of 1 or 2 minutes. For the identification of the location of Thy-1-positive structures in relation to the basement membrane, parallel sections were incubated with 1:100 antiserum to type IV collagen and visualized with rhodamine-conjugated sheep anti-rabbit $F(ab')_2$ serum (*27*). Immunocytochemistry was performed as for the indirect immunofluorescence assays with 100 μl of 75 μg FITC-labeled $F(ab')_2$ rabbit anti-rat Thy-1/ml. The sections were then incubated wtih 100 μl of 1:50 dilution of alkaline phosphatase conjugated to goat anti-rabbit IgG. The alkaline phosphatase was localized as a red color by incubation with Fast Red TR Base and napthol AS-B1 phosphoric acid (*28*). Sections were then counterstained with Mayer's hemalum and mounted in buffered glycerinated gelatin. Immunocytochemical localization of myoepithelial cells and basement membranes with the use of 1:100 dilutions of antisera to myosin (*26*) and type IV collagen (*27*) was done as for the Thy-1 antigen (Warburton MJ, Mitchell D, Rudland PS: Manuscript in preparation).

Thy-1 antigen was also localized on lactating glands by an indirect immunoperoxidase technique at the ultrastructural level. Lobuloalveolar units were dissected out with a minimum of adherent stroma and incubated in 100 μl of the monoclonal anti-Thy 1.1 serum as before for 2 hours. The specimen was washed for 15 minutes in PBS and then incubated for a further 2 hours in 100 μl of 1:10 dilution of a sheep anti-mouse serum conjugated with horseradish peroxidase (*28*). The specimen was washed for a further 15 minutes in PBS and then incubated for 5 minutes in PBS containing 0.05% (wt/vol) 3,3′-diaminobenzidine (Sigma Chemical Co.) and 0.06% (vol/vol) hydrogen peroxide. All incubations were performed at room temperature. The tissue was then fixed for 2 hours in 2% (wt/vol) glutaraldehyde and post-fixed overnight in 1% (wt/vol) osmium tetroxide at 4°C. Both fixatives were phosphate buffered (0.05 *M*; pH 7.2–7.4) and their osmolarity was adjusted to 350 mosmol by addition of sucrose. The tissue was dehydrated in a series of graded ethanols and embedded, via propylene oxide, in Epon-Araldite resin. The resin blocks were polymerized at 60°C for 48 hours. Sections for light microscopy were stained with toluidine blue in 1% borax, and ultrathin sections were cut with a diamond knife on a Reichert OM U4 microtome. Without being stained, ultrathin sections were examined directly in a Philips EM 400 transmission electron microscope at 60 kV.

Specificity of Thy-1 immunofluorescence and immunochemical localization.—The specificity of the fluorescence for Thy-1 was demonstrated by abrogation of FITC fluorescence on tissue sections and cells in culture by prior incubation of the anti-Thy-1 antiserum with *a*) a threefold molar excess of pure Thy-1 antigen (overnight, 4°C) or by *b*) rat thymocytes (10^8/100 μg $F(ab')_2$; 1 hr at 4°C). No immunofluorescence was seen when the FITC-labeled or rhodamine-conjugated $F(ab')_2$–sheep anti-rabbit $F(ab')_2$, FITC–$F(ab')_2$ goat anti-rabbit immunoglobulin, or FITC–goat anti-mouse immunoglobulin were used in the absence of Thy-1 antibodies. Controls for all antisera used were included in every experiment. The rabbit anti-rat Thy-1, monoclonal anti-Thy 1.1, and anti-Thy 1.1 alloantisera all gave the same pattern of specific immunofluorescence on tissue sections and cell lines (all rats are Thy 1.1 in type). The anti-Thy 1.2 alloantiserum gave no specific immunofluorescence. The specificity of Thy-1 immunocytochemical localization was demonstrated by abrogation of red coloration due to alkaline phosphatase activity by prior incubation of the rabbit anti-Thy-1 serum with the pure Thy-1 antigen.

Quantitative absorptions and radioactive binding assays.—The assays were done as described by Morris and Williams (*29*). Eighty microliters of 0.283 μg $F(ab')_2$ or Fab anti-Thy 1.1 antiserum/ml was absorbed at 0°C for 1 hour with treble dilutions of measured numbers of cells (in 80 μl medium). The absorbed sera were removed, after centrifugation at 12,000×*g* for 1 minute, and their remaining activity was assessed by incubation with 1×10^7 glutaraldehyde-fixed adult rat thymocytes for 1 hour at 0°C. Binding of antiserum to these target cells was determined in a subsequent incubation with ^{125}I-labeled rabbit anti-mouse immunoglobulin, and the ^{125}I that was bound was measured in a gamma counter (LKB Instruments, Inc.). For detergent extraction, 60 μl of cells (3×10^8/ml) was mixed with an equal volume of 4% Triton X-100 and kept at 0°C in PBS for 45 minutes. Sixty microliters of 30% bovine serum albumin was then added to reduce the action of the detergent, and treble dilutions of cells were set up for absorption with the monoclonal anti-Thy-1 antiserum. Controls containing the same number of cells were processed in parallel, with the use of 60 μl PBS to replace the detergent. In addition, absorptions were set up with treble dilutions of detergent-containing buffer plus antibody but *no* cells to control for the possible effect of detergent in the binding assay.

RESULTS

Thy-1 on Tissue Sections

In the normal mammary gland from 7-day-old females, ductal myoepithelial cells, identified as elongated cells just internal to the basement membrane (*30*), showed no Thy-1-positive staining (table 2). The basement membrane was visualized by antitype IV collagen immunofluorescence or by silver staining for reticulin (not shown). By day 25 of development, areas near the basement membrane and/or myoepithelial cells were weakly positive and from day 45 onward these areas showed an increase in Thy-1 immunofluorescence (table 2) (figs. 1A–1D). From that time onward myoepithelial cells could be detected in similar positions in alveolar buds and alveoli (*31*). Myoepithelial cell and/or basement membrane areas in ducts from the glands of pregnant and lactating animals were strongly Thy-1-positive. At these later stages in development, the straplike myoepithelial cells producing a basket-like pattern round the alveolar lumina were also strongly positive (not shown). Additional Thy-1-positive cell types were probably fibroblasts [elongated cells external to the basement membrane (*30*)] and fat cells (fig. 1C). Ductal and secretory alveolar epithelial cells were always Thy-1 negative. All small blood vessels were Thy-1 positive; the antigen appeared to be on the vascular basement membrane (figs. 1A–1D).

The DMBA- and MNU-induced mammary adenocarcinomas consisted in part of circular structures composed of cuboidal epithelial cells, sometimes surrounded by a layer or layers of Thy-1-positive elongated cells (figs. 1E, 1G, 1I). In addition, finger-like processes of blocks of elongated cells penetrated through the more differentiated areas of the tumors, and these processes contained cells of varying degrees of Thy-1 positivity (fig. 1G). The general pattern of staining was also observed in the Rama 25-induced tumors (not shown). Blood vessels (with the exception of major arteries) within these neoplastic tissues were Thy-1 positive with a location similar to that of normal tissues (fig. 1H). In the sarcoma tissue, derived from polyomavirus-transformed rat fibroblasts, only occasional streaks of Thy-1-positive immunofluorescence were seen, mainly associated with capillaries and nerves (fig. 1F).

[a] Tissue was from female rat. Only mammary parenchyma was considered: Nearly all capillaries, fibroblasts, and fat cells in stroma were also positive.

[b] Epithelium was always zero (–).

[c] Fluorescence intensity was recorded near (i.e., on and/or adjacent to) myoepithelial cells on the scale of zero (–) to maximum (++); ± indicates that some of the areas have positive fluorescence (+) and others have no fluorescence on the same tissue section. Six areas of each section were examined from four sections of each stage.

The localization of Thy-1 in the myoepithelial cell areas was examined in more detail with the use of an immunocytochemical technique. In the parenchyma of the normal rat mammary gland from 40-day-old female rats, Thy-1 was located in two positions and in differing concentrations: weakly on the myoepithelial cells and strongly in the region immediately adjacent to the myoepithelial cells and distal from the epithelial cells lining the ducts (figs. 2A–2D). The position of the myoepithelial cells in parallel glands was confirmed by their immunocytochemical localization with antimyosin serum (fig. 2E) (*26*) and antiprekeratin serum (not shown) (Warburton MJ, Mitchell D, Rudland PS: Manuscript in preparation). The strongly Thy-1-positive region immediately adjacent to the myoepithelial cells seemed to occur in the region of the basement membrane as visualized by immunocytochemical localization of type IV collagen in parallel glands (fig. 2F) (*27*). Thy-1 was not seen in the intercellular ground substance external to the basement membrane (fig. 2B). These results were confirmed by visualization of monoclonal antibodies to Thy-1 at the ultrastructural level in mammary glands from lactating rats. Thy-1 was predominantly in the lamina densa of the basement membrane as well as on the occasional mesenchymal cell external to the basement membrane (fig. 3). However, its distribution along the basement membrane varied. The intensity of stain was greatest when opposite a Thy-1-bearing mesenchymal cell and was gradually reduced on either side. This changed distribution of Thy-1 in the basement membrane could occur over the distance of a single myoepithelial cell (fig. 3). In these lactating glands the alveoli were so distended that the myoepithelial cells were forced apart, exposing flattened epithelial cells to the basement membrane. The basement membrane in these positions could also contain Thy-1 (not shown).

Distribution of Thy-1 on Cultured Cell Lines

All elongated (myoepithelial-like) cell lines were Thy-1 positive. This was true for lines derived from both tumor (figs. 4G–4I) and normal tissue (not shown), as well as for elongated cells developing in cultures of a cuboidal cell line (figs. 4D–4F; 5A–5F). Thus both the dual converter (e.g., Rama 75; figs. 5A–5C) and the monoconverter (e.g., Rama 102; figs. 5D–5F) cuboidal epithelial cell lines derived from normal glands yielded Thy-1-positive elongated cells. All cuboidal cell lines (figs. 4A–4C; 5A–5F) and their droplet and doming cultures (figs. 5G–5I) were Thy-1-negative (table 1). The intensity of Thy-1 immunofluorescence on myoepithelial-like cells varied from subline to subline, the more bipolar being more positive. This was demonstrated in the elongated series of cells cloned initially from Rama 25: Rama 29, Rama 29T, Rama 500, Rama 502, and Rama 503 (table 1). The cells of both fibroblastic cell lines (Rama

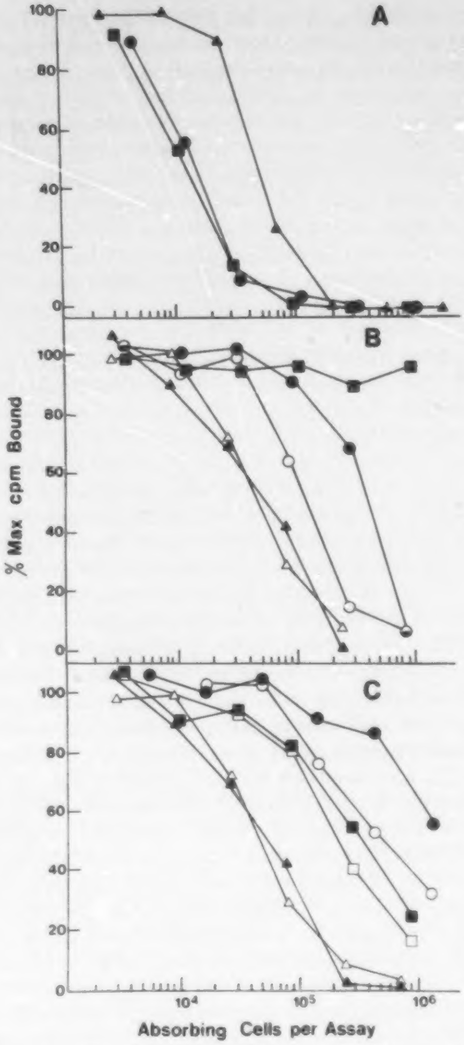
27 and Rama 300; figs. 4J–4L) gave positive staining. The fluorescence associated with Thy-1 circumscribes the cells and the antigen is probably mainly localized in their plasma membranes.

Eight different fixatives were tested: 70% ethanol (4°C), 95% ethanol (4°C), 95% ethanol–5% glacial acetic acid (4°C), 100% methanol (4°C), 75% acetone–25% methanol (−20°C), 100% acetone (−20°C), 2% paraformaldehyde (4°C), and 95% ethanol after a 5-minute treatment of the cells with 200 µg disodium EDTA/ml. All but two gave comparable levels of positive staining on Rama 27 and Rama 29 cells on cover slips. Those pretreated with EDTA appeared to be brighter, presumably owing to rounding up of the cells. However, morphologic information is lost by this shape change. One hundred percent acetone also gave slightly brighter immunofluorescent staining, but this was the direct result of a higher background.

Organized cellular structures in Rama 25 and Rama 75 cultures were also studied. The domes that occur in droplet cultures were Thy-1 negative (figs. 5G–5I). In contrast, the lumps and ridges produced predominantly by elongated cells showed positive Thy-1 immunofluorescence on these elongated cells (figs. 5J–5L).

Quantitative Studies of Thy-1 on Cell Lines

The relative amounts of surface Thy-1 were measured on Rama 25 (epithelial stem cell), Rama 29 (myoepithelial-like cells), and Rama 27 (fibroblastic cells) subconfluent cell cultures. Rama 27 and Rama 29 gave consistent results requiring $1.3\pm0.1\times10^4$ and $0.92\pm0.04\times10^4$ cells, respectively, to give 50% absorption of 20 µl monoclonal anti-Thy-1 antibody at 0.283 µg/ml: $4.3\pm0.6\times10^4$ rat thymocytes gave 50% absorption (text-fig. 1A). Thus Rama 27 cells bore 3.3 times and Rama 29 bore 4.7 times more cell surface Thy-1 molecules than did rat thymocytes, which have been shown to carry approximately 1×10^6 molecules of Thy-1 per cell (*25*). Rama 25 cuboidal cell cultures gave variable results, ranging from no absorption at all to 50% absorption with 40×10^4 cells/20 µl antiserum (text-fig. 1B), which represented a range of less than 10^4 to 1×10^5 Thy-1 molecules/cell. This variation correlated with the passage number of the cultures—the greater the passage number and hence the associated spontaneous conversion to Thy-1-positive elongated cells, the greater the absorptive capacity. Confluent cultures of Rama 25 cells grown in DMSO, hydrocortisone, insulin, and prolactin to produce droplet cells and domes gave 50% absorption values ranging from 9×10^4 to 2×10^6 cells. However, these cultures were maintained considerably longer than the subcultures of Rama 25 cuboidal cells and would therefore be expected to produce relatively more spontaneous conversions to elongated cells.



TEXT-FIGURE 1.—Quantitative absorptions of Thy-1 antisera with different cells: A) subconfluent 3-day cultures of Rama 27 (●), Rama 29 (■), and rat thymocytes (▲); B) subconfluent 3-day cultures of cuboidal Rama 25 passage 26 (■), Rama 25 passage 28 (●, ○), and rat thymocytes (▲, △); and C) confluent droplet cell cultures of Rama 25 passage 26 (●, ○), Rama 25 passage 28 (■, □) grown for 7 days in normal medium and then 2 days in DMSO-containing medium, and rat thymocytes (▲, △). *Closed symbols* are without and *open symbols* are with prior treatment of the absorbing cells with detergent. Mouse monoclonal anti-Thy 1.1 serum was absorbed with increasing numbers of cells, and the remaining unabsorbed antiserum was then titered on rat thymocytes with ^{125}I-labeled rabbit anti-mouse immunoglobulin (*see* "Materials and Methods"). The percentage of the maximum cpm bound to the thymocytes was followed as a function of increasing numbers of absorbing cells. Max=maximum.

Treatment with the detergent Triton X-100 did not increase the amount of detectable Thy-1 in Rama 27, Rama 29, and rat thymocytes. However, 5 of 5 experiments with untreated Rama 25 and 3 of 5 experiments with DMSO- and hormone-treated Rama 25 Triton extracts showed greater absorption than did the experiment with whole cells [Rama 25, whole: Triton extract=1.3 to 1.4; Rama 25 plus DMSO, whole: Triton extract=1.1 to 1.3 (text-figs. 1B, 1C)]. Thus the number of cryptic (not detectable at surface of whole cells) Thy-1 molecules per cell was approximately 3×10^5 for Rama 25 and from 0 to 8×10^4 for Rama 25 droplet cells with DMSO and hormones. The appearance of the cryptic antigen within Rama 25 cells was not an artifact of the detergent treatment for the following reasons: 1)

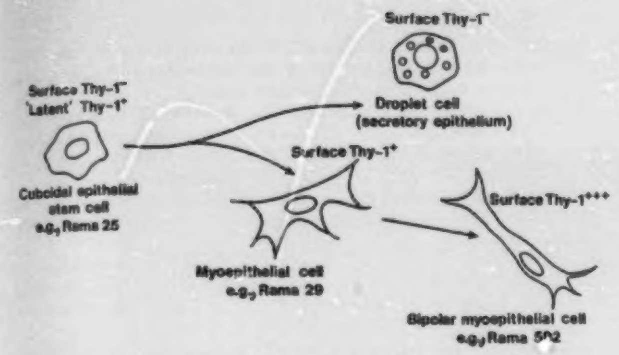
Treatment of the original binding buffers with Triton X-100 without cells failed to increase the amount of detectable Thy-1 over the background controls without Triton X-100. 2) Some cells with no detectable surface Thy-1 [e.g., rat erythrocytes (*32*)] did not exhibit increases after treatment with the detergent (not shown). 3) Other cells with appreciable amounts of cell surface Thy-1 (e.g., rat thymocytes, Rama 29, and Rama 27) failed to show any increase after treatment with Triton X-100 (text-fig. 1B, 1C). 4) Absorption of monoclonal Thy-1 antibody first with pure rat brain Thy-1, as detailed in "Materials and Methods," and then with Triton X-100-treated Rama 25 cells still yielded no detectable binding of antibodies to rat thymocytes (not shown). Thus detergent treatment did not interfere with the apparent amount of Thy-1 in those cells with or without demonstrable Thy-1 nor with antibody–antigen complexes. Finally, fluorescently labeled anti-Thy-1 serum was added to Rama 25 cells that had been made completely permeable in and fixed with 75% acetone–25% methanol at −20°C. Under these conditions weak fluorescence specifically associated with Thy-1 was seen over the entire cells, unlike the fluorescence observed with Rama 29 cultures that completely circumscribed the cells. These results are consistent with those obtained with the detergent-treated Rama 25 cells in that Thy-1 was detected at lower levels and in this case with a cellular distribution different from that observed in Rama 29 cells.

DISCUSSION

Using immunologic detection methods, we have studied the appearance of the Thy-1 antigen in the development of rat mammary tissue in two systems, in vivo (tissue sections) and in vitro (cloned cell lines). Myoepithelial cells in vivo were Thy-1 positive, although most of the antigen seemed to reside in the region of the basement membrane. This topologic association was confirmed at the ultrastructural level. The epithelium lining the lumina in both ducts and alveoli apparently lacked the antigen. The intensity of the myoepithelial Thy-1 immunofluorescence, and hence probably the amount of antigen present, increased with the development of the gland, from being negative in rats at day 7 to being strongly positive in rats at age 45 days, with a further increase during pregnancy and lactation. Inasmuch as the first mammary myoepithelial cells (elongated cells with myofilaments) appear before birth (*33, 34*), these early cells must either bear low amounts of Thy-1 antigen (not detectable by immunofluorescence) or totally lack Thy-1 antigen. This pattern of Thy-1 distribution and its increase upon maturation of the myoepithelial cells are also seen in the cloned cell lines, although the quantitative comparison with the change in vivo cannot be made as yet. All cuboidal cell lines and their droplet (alveolar-like) derivatives lack surface Thy-1. In contrast, all cloned elongated (myoepithelial-like) cell lines, as well as elongated cells developing within stem cell cultures, are Thy-1 positive, and the more mature (bipolar) elongated cell lines bear more antigen. Thus the Thy-1 antigen provides a good qualitative cell marker with which to study rat myoepithelial cell differentiation in vitro and possibly in vivo, although for the in vivo study our observation that some fibroblasts are Thy-1 positive and that the bulk of the antigen on or adjacent to myoepithelial cells is asymmetrically distributed necessitates the use of additional markers (e.g., antitype IV collagen and antimyosin antibodies) to distinguish these two cell types (*35*). These results are similar to those in the brain where Thy-1 increases approximately twentyfold during the first 3 postnatal weeks and has a predominantly neuronal distribution (*36, 37*). This cellular distribution is also mimicked by some of the rat cell lines that express other neuronal characteristics, whereas cell lines with clearly glial properties are negative for Thy-1 (*24*). However, in the brain there is a general quantitative difference with the in vivo situation since none of the central nervous system-derived lines approach the level of antigen found in adult rat brain (*24*). In the mammary gland we are unable to assess accurately the amount of antigen present on myoepithelial cells because the myoepithelial cells cannot be purified directly. However, a comparison of the relative intensities of anti-Thy-1 fluorescence on mature myoepithelial cells in vivo and elongated myoepithelial-like cells in vitro suggests that these intensities are more comparable than those on neuronal cells in vivo and in vitro. This finding may perhaps be due to the higher numbers (approximately three times) of Thy-1 molecules per cell on cultured, elongated, myoepithelial-like cells than on the neuronal cell lines carrying the maximum observed numbers of Thy-1 molecules (*24*).

Myoepithelial cells are also known to exist in DMBA-induced adenocarcinomas (*38*) and we can detect Thy-1-positive elongated cells, presumed to be myoepithelial cells, round the outside of some circular arrays of cuboidal cells. However, the positive identification of myoepithelial cells in the tumors is much more difficult to establish than in normal glands since the position of myoepithelial cells in the tumors with respect to the basement membrane is often difficult to ascertain. There exists a whole class of rather elongated cells that infiltrate the well-differentiated areas of the tumors in finger-like processes often, where extensive enough, giving rise to apparently sarcomatous areas (*6*). Many of the cells within these areas also stain with Thy-1 antiserum to varying degrees. Whether they are myoepithelial cells showing varying degrees of expression of Thy-1 antigen, fibroblasts, lymphoid, or mast cells (*7*) is uncertain. Many of these cells, however, may be myoepithelial since similar blocks of elongated cells have been produced in tumors formed by our rat mammary cuboidal cells in nude mice; and some of them were identified as of rat rather than of mouse origin (*2, 20*).

Recent studies of mouse thymocyte development have indicated that cells first acquire intracellular and/or cryptic Thy-1 at a stage prior to the one when the antigen is exposed at the cell surface (*39*). In addition, the mammary stem cell line Rama 25 may contain cytoplasmic Thy-1 (*15*). However, this finding was based on immunofluorescence after acetone fixation, a system where we find that the high background obscures specific cytoplasmic immunofluorescence. We have, therefore, used more sensitive assays (quantitative absorptions and radioimmune binding assays) both to detect and quantitate surface (whole cells) versus surface plus possible intracellular (detergent extracts of cells) Thy-



Surface Thy-1$^-$

Bipolar myoepithelial cell e.g., Rama 5P2

TEXT-FIGURE 2.—Schematic summary of the differentiation of mammary epithelial cells. Cuboidal epithelial stem cells with no detectable surface Thy-1 (Thy-1$^-$) but with latent Thy-1 (Thy-1$^+$) or cryptic Thy-1 differentiate to either droplet cells with no detectable Thy-1 (Thy-1$^-$) and reduced cryptic Thy-1 or to elongated, myoepthelial-like cells with surface Thy-1 (Thy-1$^+$) and then to bipolar myoepithelial-like cells with additional surface Thy-1 (Thy-1^{+++}), as recorded in table 1.

1. We find that subconfluent cultures of mammary epithelial stem cells (Rama 25) contain an average of 3×10^6 molecules of cryptic Thy-1 per cell. Rama 25 cultures treated with DMSO (droplet cells) contain appreciably less (0–8×10^4 molecules of cryptic Thy-1). The lower number of cryptic Thy-1 molecules per cell in the DMSO-treated Rama 25 cells possibly reflects the lower percentage of stem cells within these cultures rather than a smaller number of cryptic antigens per cell. The exact location of this cryptic Thy-1 is unknown, although by analogy with the mouse prothymocyte it could be intracellular and its correct glycosylation may be a prerequisite for exposure on the cell surface (*39, 40*). The differentiation of mammary epithelial cells (text-fig. 2) therefore involves a series of steps whereby a population of surface Thy-1-negative stem cells, at least some of which contain a pool of intracellular Thy-1, gives rise to either Thy-1-negative secretory or to surface Thy-1-positive myoepithelial cells that bear increasing numbers of Thy-1 molecules as differentiation proceeds.

Although Thy-1 provides an excellent marker molecule in certain differentiating systems, little is known of its function. It may play a role in the formation of domes in a subline of Rama 25 (*41*). This suggestion was based on the findings that Thy-1 could be detected on the surface of incipient domes (particularly at cell junctions); that, with fixatives allowing free access of the antibodies to the interior of cells, the cells showed enhanced cytoplasmic fluorescence, particularly in doming regions; and that antibodies to Thy-1 could specifically block formation of domes. We have been unable to repeat all three findings satisfactorily when using xenogeneic, allogeneic, and monoclonal antibodies to Thy 1.1 on Rama 25 cultures. However, using low protein concentrations, particularly with the monoclonal antibodies, we can observe fluorescence, especially round heterogeneities in the cell monolayer, e.g., cell junctions, domes (droplet cells), lumps, and ridges (elongated and/or myoepithelial cells). However, this fluorescence is abolished only by preabsorption of the antibodies with thymocytes and/or pure Thy-1 in the cases of ridges and lumps (figs. 5G–5L). Anti-Thy 1.1 antibodies at high concentrations can block dome formation, but this blockage could also be achieved with similar concentrations of anti-Thy 1.2 antisera that failed to show specific binding at any concentration tested. Since the original authors (*41*) used different sources of xenogeneic and monoclonal antibodies to Thy 1.1 than those used here, we cannot exclude the possibility that the reported fluorescence observed in domes with these antibodies and the prevention of formation of domes by the monoclonal antibodies (*41*) are unique for this collection of Thy-1 antisera. However, the same group (*42*) have recently reported that the anti-doming effect of their monoclonal antibodies was not removed by absorption to Thy 1.1-positive cells and was therefore unrelated to Thy-1.

In the mouse brain Thy-1 has been found in association with synaptic complexes, suggesting that it may be involved in cell to cell interaction of the neuronal elements (*43*). Recently, in the rat Thy-1 antigen has also been found in regions associated with the basement membrane surrounding some blood vessels, including the postcapillary venules in lymph node, and on interstitial connective tissue on the dermis and lamina propria. Thy-1 may, therefore, function in mediating selective adhesion of cells to connective tissue substrates and hence could be involved in controlling migration and in homing of lymphocytes during recirculation (*8, 12, 13*). In regard to the mammary gland, Radnor (*44*) has suggested that contact of mammary epithelial cells with the basement membrane may result in production of myoepithelial cells in early developmental stages. We have found that increased synthesis of some of the major constituents of basement membranes, type IV collagen and fibronectin, occurs with concomitant expression of cell surface Thy-1 molecules in cell lines cloned from Rama 25, which are intermediate in morphology between cuboidal and fully elongated forms (Warburton MJ, Ritter M, Rudland PS: Unpublished results). This finding and our observations of extracellular Thy-1 in the region of the basement membrane raise the possibility that interactions between basement membrane components and cell surface Thy-1 may be involved in controlling subsequent myoepithelial cell development and/or positioning within the mammary gland.

Surgical Resection of the Rat Colon: Effects on Carcinogenesis by 1,2-Dimethylhydrazine[1,2,3]

C. A. Rubio, *M.D., F.I.A.C.,*[4] *and* **G. Nylander**, *M.D.*[5,6]

ABSTRACT—Following a 3-month treatment with 1,2-dimethylhydrazine (DMH) given weekly (sc), outbred Sprague-Dawley rats were subjected to partial resection of the transverse colon. After surgery, DMH treatment was continued for 6 months, after which the rats were killed. At autopsy, 63% of the tumors were found in the transverse colon. By contrast, only 29% of the tumors found in the "sham-operated" control animals occurred in the transverse colon. Surgical trauma in the colon mucosa subjected to the action of carcinogenic agents appeared to promote the conditions suitable for the development of tumors in that organ.—JNCI 1982; 68:813–815.

The 5-year survival following "curative" resection for carcinoma of the colon and rectum is about 45% (*1*). The reasons for the failure to obtain permanent cures in the remaining cases are local recurrence, regional recurrence, and/or distant metastases.

The reported incidence of recurrence at the anastomotic site following surgery for colorectal tumors varies widely. Olson et al. (*2*) reported an incidence of 1.4%; Cass et al. (*3*), of 3%; Southwick et al. (*4*) and Goligher et al. (*5*), of 10%; Beal and Cornell (*6*), of 15%; and Welch and Donaldson (*7*), of 33%. The true mechanism responsible for the development of local recurrences at the suture line remains unknown; Morgan and Lloyd-Davis (*8*), Goligher et al. (*9*), Southwick and Cole (*10*), and Cole (*11*) believe that local recurrences at or near the suture line following resection for cancer of the colon are the result of implantation of cancer cells from the tumor into the suture line during surgery (text-fig. 1). On the basis of this theory, several intraoperative treatments have been proposed for destruction of the cells desquamating from the tumor. The use of these procedures, however, has not resulted in lower numbers of anastomotic recurrences as reported in well-documented studies (*10*). Thus the results of intraoperative procedures, aimed at preventing recurrences by sterilizing tumor cells, have been contradictory.

The cause of recurrence at colon anastomotic sites in humans is also thought to be due to microscopic cancer cells left in the tissues adjacent to but outside the line of anastomosis. After surgery these nests of cancer cells may grow and invade the anastomosis from the outside.

We reported an increased incidence of experimentally induced colon tumors in animals previously subjected to colon surgery (*12*, *13*). In those experiments, segments of colon were excised and retransplanted in the abdominal wall by the method of Thiry-Vella. In light of these results we investigated whether a minor surgical trauma in the colon mucosa subjected to the action of a carcinogen could promote the development of tumors at the site of surgery.

MATERIALS AND METHODS

Thirty-six male outbred Sprague-Dawley rats (Anticimex, Stockholm, Sweden) averaging 200 g in weight were studied. Of the 36 rats, 26 received sc 21 mg DMH/kg body weight suspended in 1 ml EDTA solution (as stabilizing agent), once a week for 3 months.

At 3 months, 16 of the 26 rats were subjected to partial resection of the transverse colon (the transverse colon is herein considered 4 cm distal to the hepatic flexure). The resection was done approximately 2 cm distal to the hepatic flexure. The animals were anesthetized with mebumal–ether, and a ring of about 2 mm in width of transverse colon was removed and fixed in 10% neutral Formalin for histologic examination. An end-to-end anastomosis of the transverse colon was done with the use of a chromic catgut.

The remaining 10 animals were "sham operated." (The transverse colon was massaged for 5 min but no resection was done.) One week after the operation, the treatment with weekly injections of DMH was continued for another 27 weeks.

The remaining 10 of the 36 rats received sc injections of EDTA once a week for 3 months. After 3 months the animals were operated on under mebumal–ether anesthesia, and a 2-mm-wide segment of the transverse colon was removed. The weekly sc injection of EDTA was continued after the surgery until the end of week 27.

At the end of the observation period all animals were killed, and the presence of tumors in the various colon segments was noted.

RESULTS

All 26 animals receiving DMH developed colon tumors (tables 1, 2). None of the operated rats receiving vehicle developed tumors. In the 16 operated animals receiving DMH, 24 tumors developed in the colon and/or rectum (i.e., 1.5 tumors/animal; table 1). In the sham-operated group of animals receiving DMH, 14 tumors developed (i.e., 1.4 tumors/animal; table 2). The highest number of tumors found in the group treated with DMH and partial resection was 2 tumors/animal. A similar result was obtained in sham-operated animals receiving DMH.

ABBREVIATION USED: DMH=1,2-dimethylhydrazine.

Exfoliated tumor cells
A
Implantation of tumor cells in suture line
B
D
Carcinogen + Hemodynamic + Cell proliferative alterations
C

TEXT-FIGURE 1.—Local recurrence of cancer at or near the suture line following resection of colon for cancer is believed to be due to implantation of exfoliating tumor cells (A) in the suture line (B). The alternative mechanism is proposed: DMH (and probably environmental colonotropic carcinogens) induces cellular aberrations in the colon mucosa. Partial colon resection promotes at the anastomotic site a mechanism of repair, which is achieved by colon cells having aberrations (C). Aberrant cells may incite malignant transformation (D) during the process of local repair in the colon mucosa.

Of the 24 tumors in animals treated with DMH and partial resection of the colon, 63% were found in the transverse colon. In the sham-operated animals, only 29% of the 14 tumors were located in the transverse colon. The difference between these 2 groups was significant ($P<0.001$).

TABLE 1.—*Number of tumors in the colon and rectum in 16 rats treated with DMH*[a]

Type of tumor	No. of tumors				
	Ascending colon	Transverse colon	Descending colon	Rectum	Total
Invasive adenocarcinoma	1	9	6	1	17
Adenoma	1	6	0	0	7
Total	2	15	6	1	24

[a] Rats were treated with DMH for 3 mo and then operated on, with minimal resection of the transverse colon. DMH treatment was continued after the operation for an additional 3 mo. Results were obtained after 6 mo of DMH treatment.

TABLE 2.—*Number of tumors in the colon and rectum in 10 rats treated with DMH*[a]

Type of tumor	No. of tumors				
	Ascending colon	Transverse colon	Descending colon	Rectum	Total
Invasive adenocarcinoma	4	3	4	0	11
Adenoma	1	1	1	0	3
Total	5	4	5	0	14

[a] Rats were treated with DMH for 3 mo and then sham operated. DMH treatment was continued after the operation for an additional 3 mo. Results were obtained after 6 mo of DHM treatment.

The histologic examination of resected colon segments obtained at surgery 3 months after the initiation of the DMH treatment revealed normal histology only. No signs of atypical epithelium or tumors could be found in these segments.

Of the 24 tumors found in the operated group and receiving DMH, 7 were tubular adenomas with varying degrees of epithelial atypia and the remaining 17 were invasive adenocarcinomas. Of the 15 tumors found in the transverse colon, 6 were adenomas and the remaining 9 were invasive adenocarcinomas. Of the 14 tumors found in the 10 sham-operated rats receiving DMH, 3 were tubular adenomas with varying degrees of epithelial atypia and the remaining 11 were invasive adenocarcinomas. Of the 4 tumors found in the transverse colon, 1 was an adenoma and the rest were invasive adenocarcinomas.

DISCUSSION

Protracted treatment of rodents with colonotropic carcinogens induces colon tumors (*14*). These tumors are usually circumscribed, and their histologic features vary from tubular adenoma to nonmucus- and mucus-producing invasive adenocarcinomas. The development of circumscribed lesions indicates that those experimental tumors are local manifestations of an ongoing cancer process taking place in the colon mucosa as a whole. The causes of the local tumor development remain obscure.

Partial colon resection can induce, at anastomosis and near anastomosis, hemodynamic and cell proliferative mechanisms of repair. Under normal conditions, complete healing would be achieved some time after the operation. In our experimental model the carcinogenic substance may have induced aberrations in the epithelial cells, thus interfering with the normal mechansisms of repair. Those epithelial aberrations may have triggered the mechanism(s) leading to malignant transformation.

While the tumor incidence was high in the transverse colons of operated animals, a parallel decrease in tumor incidence was observed in the distal colons of these animals. The causes for this phenomenon remain obscure.

No special markers were used to indicate the site of anastomosis during the operation. This procedure was followed to avoid difficulties in interpretation of final results due to the possible association between foreign bodies, carcinogens, and tumor development. Thus identification of the anastomotic suture line in the transverse colon at autopsy has been difficult. Therefore, whether the tumor developed primarily at or near the anastomotic suture line is not known.

Oscarson et al. (*15*) and Williamson et al. (*16*) demonstrated in rats that the resection of the small bowel increased the incidence of experimental colon tumors. Compensatory hyperplasia in the colon was considered to be a predisposing factor to the development of neoplasia in the residual adapted bowel. In those experiments, extensive resection of the small intestine and large bowel was done, with the colon carcinogen being injected almost simultaneously (*15, 16*). By contrast, in our model only a minimal segment of the colon was resected at the time that the mucosa was probably saturated with the carcinogen (after 3-mo treatment). Although marked compensatory mucosal hyperplasia as shown after extensive bowel resection (*15, 16*) probably did not occur in our model, the possibility of minimal local hyperplasia preceding tumor formation could not be ruled out.

Our results indicate: *a*) that the local tumors may develop following resection of the transverse colon in the absence of previously exfoliated tumor cells and *b*) that surgical trauma in the colon mucosa subjected to the action of carcinogenic agents may promote conditions suitable for development of tumors.

Intracerebral Adoptive Immunotherapy of a Murine Lymphoma Antigenically Altered by Drug Treatment In Vivo[1, 2, 3]

L. Romani,[4] M. C. Fioretti,[4] R. Bianchi,[4] B. Nardelli,[4] *and* **E. Bonmassar[4, 5]**

ABSTRACT—Intracerebral tumor neutralization assay and adoptive immunotherapy with in vitro sensitized lymphocytes were done in immunodepressed mice challenged intracerebrally with L5178Y/DTIC lymphoma, a tumor subline antigenically altered by treatment with 5-(3,3-dimethyl-1-triazenyl)-1H-imidazole-4-carboxamide (DTIC) in vivo. Primary cytotoxic T-lymphocytes (CTL) were generated in vitro against L5178Y/DTIC cells with the use of splenocytes of histocompatible (BALB/cCr × DBA/2Cr)F_1 donors. The extent of antitumor activity of CTL was evaluated by the measurement of tumor cell proliferation in the brain, as judged by the ^{125}I-labeled 2′-deoxyuridine uptake values and by survival times of recipient mice. The results of the experiments showed: *a*) CTL were highly effective in inhibiting tumor growth when they were injected along with L5178Y/DTIC tumor cells in a Winn-type neutralization assay; *b*) the tumor inhibition mediated by CTL was specific, since no antilymphoma effects were detected when CTL sensitized against L5178Y/DTIC line were admixed with the parental L5178Y tumor or with other unrelated lymphoma cells; and *c*) local adoptive immunotherapy with CTL given on day 1, 3, or 5 after the intracerebral challenge with L5178Y/DTIC lymphoma substantially impaired tumor cell proliferation and significantly increased survival times of recipient leukemic mice.—JNCI 1982; 68:817–822.

The possibility of increasing antitumor responses by enhancing the immunogenic strength of cancer cells following treatment of tumor-bearing hosts was previously demonstrated (*1, 2*). Both in vivo and in vitro treatments of murine lymphoma cells with an antineoplastic agent (i.e., DTIC) (*3, 4*) have been found to increase markedly tumor cell immunogenicity. The new transplantation antigens detectable in DTIC-treated tumor cells, referred to as DMTA (*5*), were found to elicit specific transplantation resistance (*6*) and cell-mediated cytotoxic responses by sensitization in vivo (*7*) and by a primary (*8*) or secondary (*9*) response in vitro.

It has been established that immunogenic tumors can be treated successfully with adoptive transfer of in vivo sensitized lymphocytes (*10, 11*). More recently, it has been shown that in vitro generated CTL are also effective against murine neoplasias in a Winn assay-type model (*12, 13*) or in immuno-chemotherapy protocols (*13*). In addition, nonimmune spleen cells produced minimal (*14*) or no antitumor effects (*15*).

In the present study the therapeutic efficacy of primary CTL sensitized against DMTA was evaluated with the use of an ic tumor model. A Winn-type neutralization assay and adoptive immunotherapy were performed on the brain.

The brain is an immunologically privileged site (*16*), although a weak allograft response can be demonstrated in the brain against histoincompatible normal (*17*) or tumor cells (*18*). Therefore, the transfer of sensitized lymphocytes could supplement the brain with immunocompetent cells capable of impairing the progressive growth of an immunogenic tumor inoculated in this organ.

Our results showed that local adoptive immunotherapy can be successfully applied in the brain when the target lymphoma cells were rendered highly immunogenic after DTIC treatment in vivo.

MATERIALS AND METHODS

Animals.—(BALB/cCr × DBA/2Cr)F_1 (CD2F_1; *H-2*^{d}/*H-2*^{d}) and (C57BL/6Cr × DBA/2Cr)F_1 (BD2F_1; *H-2*^{b}/*H-2*^{d}) mice were obtained from the National Cancer Institute, Bethesda, Md. Both sexes of mice ranging in age from 2 to 4 months were used.

Tumors.—Chemically induced ascitic leukemia L5178Y (*19*) of DBA/2 origin and Rauscher virus-induced leukemia RBL-5 of C57BL/6 origin (*20*) were maintained in histocompatible mice by weekly ip injection of 10^6–10^7 cells. Lymphoma L5178Y/DTIC was obtained by DTIC treatment of the original line L5178Y, as previously described (*21*), and was routinely maintained in CD2F_1 mice immunosuppressed with cyclophosphamide (180 mg/kg ip) 6 hours before challenge.

In vitro sensitization.—The in vitro primary cytotoxic lymphocytes were obtained as previously described in detail (*8*); 35×10^6 viable "responder" CD2F_1 spleen cells were cocultured with 8.7×10^5 irradiated (5,000 rad in vitro delivered by ^{60}Co irradiator; HOT SPOT MKIV, United Kingdom Atomic Energy Authority, Horwell, England) L5178Y/-DTIC "sensitizer" tumor cells (responder:sensitizer ratio of 40:1) in 25-cm^2 tissue culture flasks (Costar, Cambridge, Mass.) in a final volume of 20 ml of enriched RPMI-1640 medium (*8*). The cultures were incubated in an upright

[5] We thank Dr. J. Mayo, Mr. C. Reeder, and Dr. V. L. Narayanan, National Cancer Institute, Bethesda, Md., for supplying many of the animals and drugs that we used. We are also grateful to Mr. Mario Andrielli, Institute of Pharmacology, University of Perugia, for his expert technical assistance.

position at 37°C in a 5% CO_2-humidified atmosphere. On the 5th day, the lymphoid cells were harvested, pooled, and centrifuged for 10 minutes at 200×*g*. A viable cell count was performed and CTL were divided into two fractions, one of which was assayed by the ^{51}Cr release assay in vitro and the other by the neutralization assay and immunotherapy experiments.

^{51}Cr release microcytotoxicity assay.—Mixtures of 10^4 labeled target cells and 2×10^6 cytotoxic "attacker" lymphocytes, in a final volume of 0.2 ml, were incubated for 4 hours at 37°C in a 5% CO_2 atmosphere with the use of U-shaped 96-well microtiter plates (C.A. Greiner and Söhne, Nürtingen, Federal Republic of Germany). At the end of the incubation period, the plates were centrifuged (800×*g* for 10 min), and 0.1 ml of the supernatant was counted in a γ-scintillation counter (model 5142; Packard Instrument Co., Downers Grove, Ill.). Experimental results were expressed as the percentage of specific lysis calculated as previously described (*8*).

Intracranial transplantation procedure.—The ic inoculum procedure was previously described (*18*). Tumor cells were suspended in a volume of 0.03 ml of RPMI-1640 medium and injected under sterile conditions through the center-middle area of the frontal bone to a 2-mm depth with the use of a 0.1-ml glass microsyringe (Hamilton Co., Reno, Nev.) and a 27-gauge disposable needle.

Evaluation of lymphoma cell growth at the brain level.—The growth of the lymphoma cells injected ic was monitored with a radioisotopic technique detailed elsewhere (*22*). 5-Fluoro-2′-deoxyuridine (25 μg) and [^{125}I]dUrd (0.5 μCi) were admixed and injected ic in a total volume of 0.03 ml of RPMI-1640 medium. Three hours later, the brains were removed and soaked in 95% ethyl alcohol for 3 days according to Bennett's technique (*23*) or collected 24 hours after [^{125}I]dUrd administration without ethanol extraction. The radioactivity was read in a γ-scintillation counter and expressed as the geometric mean of the percent of [^{125}I]dUrd uptake with respect to the amount of labeled compound injected. The survival times were also recorded by observation of mice for at least 60 days after ic injection, and tumor growth was documented by macroscopic observation at autopsy.

Tumor neutralization assay.—A modified Winn assay was employed. A mixture of a graded number of CTL and tumor cells at various ratios (CTL:tumor cells=100:1, 50:1, and 25:1) was immediately injected ic in a total volume of 0.03 ml of RPMI-1640 medium. The tumor growth rate was assessed as described above.

Adoptive immunotherapy.—Groups of 6–8 mice were inoculated ic with lymphoma cells at the desired concentration. At different days after challenge, 10^7 CTL were injected ic. The results were expressed as in the Winn assay experiments.

Irradiation of mice.—Mice were irradiated at room temperature with a ^{60}Co irradiator delivering γ-rays at 900 rad/minute.

Statistical analysis.—Differences in survival times were analyzed according to the Mann-Whitney *U* test. Data concerning [^{125}I]dUrd uptake were statistically evaluated with the use of Student's *t*-test calculated on the logs of the original cpm.

RESULTS

Intracerebral Growth of L5178Y/DTIC Lymphoma Cells

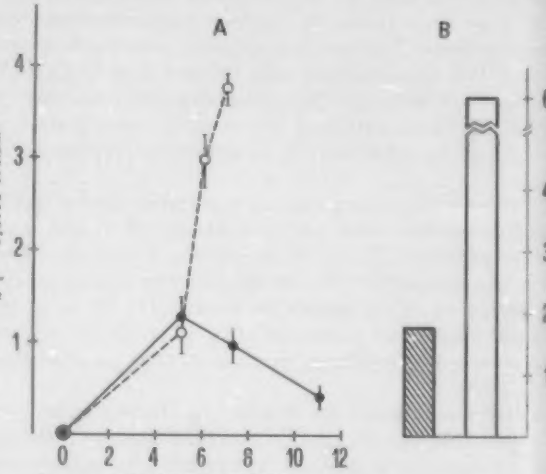
Intact or immunodepressed (400 rad) $CD2F_1$ mice were given ic injections of 10^6 cells of the L5178Y/DTIC subline. The growth of tumor cells was monitored on days 5, 6, 7, and 11 after challenge by measurement of the [^{125}I]dUrd uptake in the brain. Additional groups of mice not subjected to the [^{125}I]dUrd uptake test were utilized for survival studies.

The results in text-figure 1 indicate that the immunogenic line grew progressively in intact or immunodepressed hosts until day 5 after challenge. Later, tumor cell proliferation declined in nonimmunodepressed recipients, whereas [^{125}I]-dUrd increased markedly in the brains of irradiated mice. Mortality data confirm that lethal tumor growth occurred in immunodepressed hosts, whereas L5178Y/DTIC lymphoma cells were rejected in intact recipients.

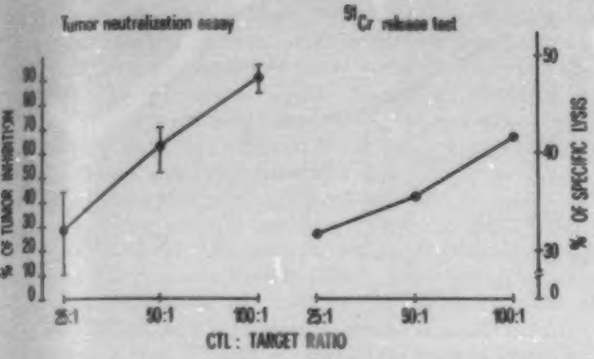
Intracerebral Tumor Neutralization Assay

Spleen cells of $CD2F_1$ donors were cocultured in vitro with irradiated L5178Y or L5178Y/DTIC tumor cells. Under optimal experimental conditions, immune lymphocytes were markedly cytotoxic against L5178Y/DTIC but not against L5178Y cells, in accord with results of previous studies (*8*).

The antitumor effects of anti-L5178Y/DTIC lymphocytes were evaluated in irradiated $CD2F_1$ mice by ic injection of a mixture of CTL and 10^5 L5178Y/DTIC lymphoma cells at CTL:tumor ratios of 100:1, 50:1, and 25:1. A portion of sensitized lymphocytes was also assayed by the ^{51}Cr release test at different CTL:target cell ratios. The extent of tumor growth was evaluated on day 7 after injection, with the use



TEXT-FIGURE 1.—Growth and rejection of 10^6 cells of L5178Y/DTIC lymphoma in the brains of $CD2F_1$ mice. [^{125}I]dUrd uptake values (A) in the brains of intact (●——●) or irradiated (400 rad; ○- - - -○) mice or survival times (B) of intact (▨) or irradiated (□) recipients. Background [^{125}I]dUrd uptake (i.e., isotope uptake in the brains of nonleukemic mice) did not exceed 0.20% in either intact or irradiated mice.



TEXT-FIGURE 2.—Winn-type neutralizing activity (ic) and in vitro cytolytic effects of CTL against L5178Y/DTIC lymphoma cells. Graded numbers of CTL admixed with 10^5 L5178Y/DTIC cells were inoculated ic into irradiated (400 rad) CD2F$_1$ mice. Tumor growth was evaluated by the [^{125}I]dUrd uptake in the brain tested on day 7 after challenge. The percentage (geometric mean) of isotope uptake in the brains of mice inoculated with lymphoma cells alone or CTL alone was 3.87 (mean + SE, 4.52; mean − SE, 3.27) or 0.19 (mean + SE, 0.26; mean − SE, 0.13), respectively.

of the [^{125}I]dUrd uptake technique. Tumor cell proliferation was markedly impaired (text-fig. 2) when CTL were admixed with lymphoma cells at CTL:tumor cell ratios of 100:1 and 50:1. At a ratio of 25:1 tumor growth was not significantly inhibited. A parallel study with the ^{51}Cr release test also pointed out that marked cytolytic activity against the DTIC lymphoma subline was provided by the CTL used for the tumor neutralization assay (text-fig. 2).

A mixture of CTL against L5178Y/DTIC and 10^5 L5178Y/DTIC tumor cells at a CTL:tumor ratio of 100:1 was injected ic into immunodepressed CD2F$_1$ mice. Two additional groups of intact or immunodepressed hosts were inoculated ic with 10^5 cells of the same lymphoma line. The [^{125}I]dUrd uptake test was performed on day 7 after injection, and the mortality of the recipient mice was recorded in a parallel experiment (text-fig. 3). Tumor cell proliferation was markedly impaired when CTL were admixed with the lymphoma, as judged by the [^{125}I]dUrd uptake values. Comparable inhibition of tumor growth was also found in nonimmunodepressed recipients. No intact animals challenged with DTIC lymphoma cells died, whereas all irradiated hosts died with evidence of ic leukemia growth. However, if they were inoculated with tumor cells admixed with specifically sensitized CTL, immunodepressed recipients survived beyond the 60-day observation period. In contrast, lethal tumor growth occurred in irradiated mice when given injections of L5178Y/DTIC cells along with fresh nonsensitized CD2F$_1$ splenocytes. A similar result was obtained with normal splenocytes cultivated without antigenic stimulus for 5 days, which actually facilitated tumor growth to some extent (data not shown).

Requirement of Viable CTL for Tumor Neutralization

CTL generated in vitro against L5178Y/DTIC subline were exposed to 10,000 rad or disrupted by freezing-thawing four times. The viability after treatments, judged by the trypan blue exclusion test, was unchanged in irradiated cells, whereas it was markedly reduced (ranging from 4 to 8%) in frozen and thawed CTL. Irradiated or frozen-thawed CTL were incapable of lysing L5178/DTIC cells (table 1) or of protecting mice inoculated ic with the same lymphoma in a Winn-type neutralization test (table 1).

Specificity of CTL for Tumor Neutralization

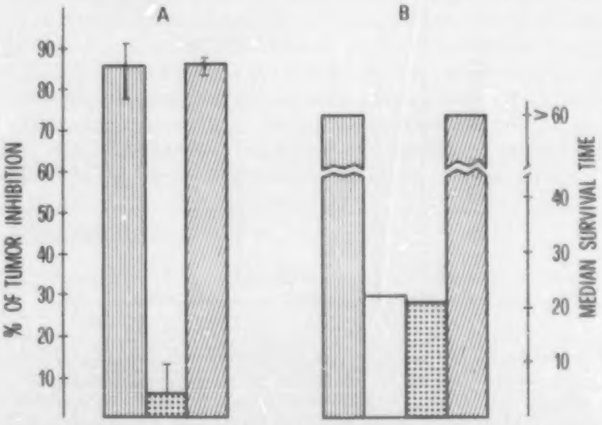
Splenocytes from CD2F$_1$ donors were sensitized in vitro against L5178Y/DTIC or allogeneic RBL-5 tumor cells. Anti-RBL-5 or anti-L5178Y/DTIC lymphocytes were admixed with L5178Y/DTIC cells (CTL:tumor ratio of 100:1) and inoculated ic into irradiated (400 rad) CD2F$_1$ hosts. We completed the experiment by admixing CTL sensitized against L5178Y/DTIC or RBL-5 lines with RBL-5 cells (CTL:tumor ratio of 100:1) and injecting the mixture into the brains of immunodepressed (400 rad) BD2F$_1$ recipients.

The results, expressed as percentages of tumor inhibition measured on day 7 after challenge, show that CTL anti-RBL-5 were unable to prevent tumor growth of the DTIC subline. In turn, CTL anti-L5178Y/DTIC did not impair the proliferation of RBL-5 cells. On the contrary, specifically immune CTL were highly effective in inhibiting the lymphoma cells used for in vitro sensitization (text-fig. 4).

When effector cells were tested against the parental L5178Y line or against the *H-2*-compatible but antigenically unrelated LSTRA lymphoma, no significant impairment of tumor cell proliferation was observed. (*See* legend to text-fig. 4.)

Adoptive Immunotherapy in the Brain

Adoptive immunotherapy with CTL sensitized against L5178Y/DTIC was performed with the use of immunodepressed CD2F$_1$ mice that were given ic injections of 10^5 cells



TEXT-FIGURE 3.—Winn-type neutralization assay in mice challenged ic with 10^5 cells of L5178Y/DTIC lymphoma. Inhibition of brain [^{125}I]-dUrd uptake (A) or median survival times (B) of *a*) immunodepressed mice inoculated with lymphoma cells admixed with 10^7 CTL (▥); *b*) immunodepressed mice inoculated with lymphoma cells admixed with 10^7 fresh, nonsensitized splenocytes (▦); *c*) immunodepressed mice challenged with lymphoma cells alone [percentage (geometric mean) of [^{125}I]dUrd uptake 7 days after tumor challenge, 3.00 (mean + SE, 3.27; mean − SE, 2.42)] and median survival time (□); and *d*) nonimmunodepressed mice inoculated with lymphoma cells alone (▨).

of L5178Y/DTIC lymphoma. The animals were inoculated ic with 10^7 CTL 1, 3, or 5 days later. Then 7 days after tumor challenge the extent of brain [^{125}I]dUrd uptake was measured. Tumor growth was significantly impaired (text-fig. 5A) in all cases, although the efficiency of CTL-mediated inhibition of L5178Y/DTIC lymphoma decreased progressively with the time elapsing between tumor challenge and adoptive transfer. No effect was detected with the use of fresh or in vitro cultured nonsensitized spleen cells (data not shown).

TABLE 1.—*Effect of different treatments of CTL on their antitumor activity in the Winn-type neutralization assay*

Type of CTL used[a]	Percent [^{125}I]dUrd uptake[b]	P[c]	Percent specific lysis[d]	Mortality data	
				MST[e]	D/T[f]
No CTL	1.71 (2.23–1.32)			18	6/6
Untreated CTL	0.17 (0.24–0.12)	<0.01	49.0±0.7	>60	0/6
FT-CTL	3.13 (3.88–2.52)	NS	7.3±1.0	19	6/6
X-CTL	1.68 (2.07–1.36)	NS	11.4±0.3	19	6/6

[a] CTL sensitized in vitro against L5178Y/DTIC tumor cells were admixed with 10^5 cells of the same lymphoma (CTL:tumor ratio of 100:1) and injected ic into immunodepressed CD2F$_1$ mice. FT-CTL=CTL disrupted by freezing-thawing four times. X-CTL=CTL inactivated by exposure to 10,000 rad in vitro.

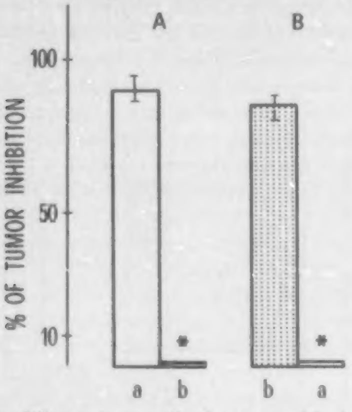
[b] The [^{125}I]dUrd was given ic on day 7 after tumor challenge. The [^{125}I]dUrd uptake of background untreated brains was 0.15 (0.18–0.12), and no significant [^{125}I]dUrd uptake increase was found in the brains of mice inoculated with CTL, FT-CTL, or X-CTL alone. *Numbers in parentheses* indicate geometric mean + SE and geometric mean – SE, respectively.

[c] Probability values were calculated according to Student's *t*-test, in which the uptake values found in mice challenged with lymphoma cells alone (i.e., no CTL) were compared with those found in mice inoculated with CTL plus tumor cells. NS=not significant.

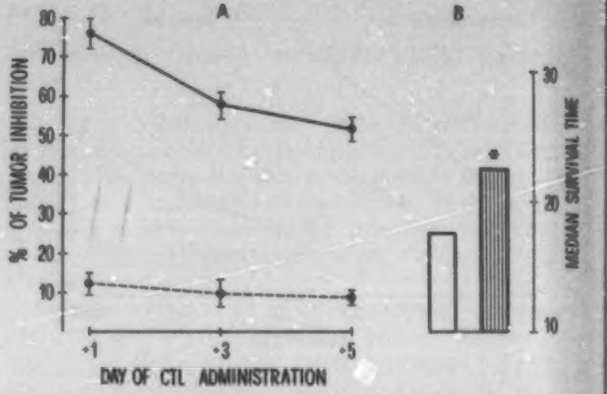
[d] Attacker:target cell ratio of 100:1. Values are expressed as arithmetic mean percent ± SE.

[e] Median survival time in days.

[f] No. of dead mice/total No. of mice tested.



TEXT-FIGURE 4.—Winn-type neutralization assay with the use of CD2F$_1$ CTL immune against L5178Y/DTIC (a) or RBL-5 (b) lymphomas, admixed with tumor cells and injected in the brains of immunodepressed mice: CTL-mediated inhibition of the growth of L5178Y/DTIC (10^5) cells inoculated into CD2F$_1$ brain (A) or of RBL-5 (5×10^3) cells inoculated into BD2F$_1$ brain (B). The ic growth of L5178Y/DTIC and RBL-5 tumor cells, in terms of percent (geometric mean) [^{125}I]dUrd uptake 7 days after tumor challenge, was 2.80 (mean + SE, 3.92; mean – SE, 2.01) and 4.37 (mean + SE, 5.47; mean – SE, 3.50), respectively. In this experiment CTL anti-L5178Y/DTIC lymphoma did not show antitumor activity when it was admixed with the parental L5178Y line or unrelated LSTRA lymphoma and inoculated at CTL:tumor ratio of 100:1 into CD2F$_1$ recipients. The percent of tumor inhibition did not exceed 10% in both cases and was not statistically significant. *P<0.01.



TEXT-FIGURE 5.—Adoptive immunotherapy with CTL, sensitized in vitro against L5178Y/DTIC lymphoma, at various days after ic tumor injection. A) Inhibition of brain [^{125}I]dUrd uptake (7 days after tumor challenge) in immunodepressed CD2F$_1$ mice inoculated ic with 10^5 L5178Y/DTIC cells (●——●) or 5×10^2 L5178Y parental line (●- - -●) and with CTL (CTL:tumor cell ratio of 100:1). B) Median survival times of irradiated mice given L5178Y/DTIC lymphoma (□) or L5178Y/DTIC plus CTL 3 days after tumor challenge (▥). *P<0.05; probability was calculated according to the Mann-Whitney U test, in which mortality data on mice inoculated with tumor cells alone were compared with those on leukemic recipients treated with CTL 3 days after tumor challenge. The percent inhibition of L5178Y/DTIC tumor growth provided by fresh, nonsensitized lymphocytes [injected 1 (+1), 3 (+3), or 5 (+5) days after tumor challenge] was –43, –26, and –17, respectively, the negative values indicating tumor growth enhancement. Median survival time of mice treated 3 days after tumor challenge with nonsensitized lymphocytes was not significantly different from that of untreated mice.

The effectiveness of CTL against L5178Y/DTIC was also confirmed in mortality studies conducted in parallel. The results (text-fig. 5B) show that recipient mice challenged with L5178Y/DTIC and inoculated ic with CTL 3 days after tumor challenge survived significantly longer than untreated controls.

No therapeutic effect of anti-L5178Y/DTIC CTL was detected in the same immunotherapy model when the L5178Y parental line was used for tumor challenge, as evident by the percentages of tumor inhibition (text-fig. 5A). Moreover, the life-spans of animals inoculated ic with the parental line and treated with CTL were not prolonged (data not shown).

DISCUSSION

The present study points out that the ic growth of a murine lymphoma rendered immunogenic by pharmacologic manipulation can be impaired by an ic transfer of CTL sensitized in vitro against the same tumor.

A number of studies performed in our laboratory (*1*, *3*, *6*, *8*) and elsewhere (*2*, *7*) provided convincing evidence that drug treatment of tumor-bearing hosts leads to a substantial increase of tumor immunogenicity, in terms of either greater density of preexisting tumor-associated transplantation antigens (*24*) or generation of novel antigenic determinants [DMTA (*5*)]. The immunogenic strength of murine lymphoma lines treated for serial transplant generations with DTIC appears to be extremely great, being comparable to that of *H-2* incompatible leukemias (*25, 26*).

The present investigation showed that the L5178Y/DTIC subline can be rejected in the brains of nonirradiated CD2F$_1$ recipients (text-fig. 1B), whereas lethal lymphoma growth occurs in immunodepressed hosts. These data provide additional emphasis on the extremely high levels of L5178Y/DTIC immunogenicity, since weak allograft responsiveness (*18, 27*) and essentially no natural resistance (*28*) are detectable in the mouse brain.

The growth rate of L5178Y/DTIC was also tested in the brains of either intact or irradiated mice (text-fig. 1A) with the use of ic uptake of [^{125}I]dUrd. A similar technique was developed by Shapiro (*29*), using the labeled DNA precursor [^{3}H]thymidine. There is a large consensus that both techniques provide reliable methods for estimating cell proliferation (i.e., DNA synthesis) of either normal (*30*) or tumor tissues (*31*).

The adoptive transfer of in vitro specifically sensitized CTL for immunotherapy of experimental tumors has been tested by various investigators (*12, 13*). The results of these studies showed that CTL alone can provide limited therapeutic effects, although CTL combined with chemotherapy gives a stronger protection (*32*).

The tumor model adopted in the present investigation appears to be quite different from models described in the literature for localized or generalized tumor growth outside the CNS. The inoculation of lymphoma cells ic is followed by a rapid and relatively localized growth in mouse brain, leading to early death of the host (*18*). Histologic observations conducted on the host harboring the L5178Y/DTIC growth show that lymphoma cells infiltrate a large zone of the hemisphere where the tumor was injected (data not shown). However, the autopsy conducted on animals that died following ic tumor inoculation did not reveal extensive leukemia growth in the peripheral organs such as spleen, liver, or lungs, similar to that detected in mice dying with generalized lymphoma. Therefore, presumably, in the present study most mice succumbed to localized leukemia growth in the CNS.

The Winn assay-type experimental results (text-figs. 2–4) are consistent with the hypothesis that specific cytotoxicity against L5178Y/DTIC cells can take place in the brain environment, when in vitro generated CTL are in close contact with target lymphoma cells. This phenomenon was evident either in terms of inhibition of [^{125}I]dUrd uptake in the brain (text-figs. 2, 3A, 4) or in terms of protection from lethal leukemia growth (text-fig. 3B). However, nonsensitized lymphocytes, obtained fresh or obtained after culture of splenocytes without antigenic stimulus, did not impair the ic lymphoma growth (text-fig. 3).

The requirement for viable lymphocytes was confirmed by data given in table 1. Moreover, the specificity of CTL was demonstrated by the following observations: *a*) failure of anti-L5178Y/DTIC CTL to afford protection against the *H-2*-unrelated RBL-5 lymphoma (text-fig. 4); *b*) failure of the same CTL to impair the growth of the parental L5178Y line or of the *H-2*-identical but etiologically unrelated Moloney leukemia virus-induced LSTRA line (*see* legend to text-fig. 4); and *c*) failure of anti-RBL-5 CTL to inhibit the ic growth of the L5178Y/DTIC subline (text-fig. 4). All these data are consistent with those of previous in vitro cytotoxicity studies, which favored the hypothesis of the presence of membrane antigens on L5178Y/DTIC cells not detectable in the line of origin [i.e., DMTA (*8*)] and noncross-reactive with those of other lymphomas homozygous for the same *H-2* haplotype or differing with regard to the *H-2* complex (*33*).

Having demonstrated that the brain environment does not impair the antilymphoma effectiveness of CTL, we took a further step to test whether CTL when transferred directly into the brain parenchyma could be used for immunotherapy protocols. The results shown in text-figure 5 provided evidence that CTL can be considered of therapeutic value in this experimental design, as shown by the significant reduction of lymphoma cell growth and increase in the lifespan of treated recipients over that of untreated controls. The decline of CTL-mediated protection with increasing time between tumor challenge and CTL transfer is not unexpected since lymphoma cell multiplication within the CNS produces a rapid increase in the number of target cells, thus reducing the effector-to-target cell ratio.

Studies not illustrated in the present communication showed that ^{51}Cr-prelabeled CTL diffuse within the brain early after cell transfer ic. This result would account for the effectiveness of effector lymphocytes even when injected 3 days after tumor challenge, i.e., when lymphoma cells extensively infiltrate the brain parenchyma. In fact, CTL diffusion appears to be a prerequisite for the cell-to-cell contact needed for killer lymphocytes to mediate cytotoxic effects against neoplastic cells in tumor-bearing hosts (*34*).

It is well known that the CNS infiltration by leukemia cells is a serious complication of the lymphomatous disease (*35–37*). Therefore, the present approach seems to open up new perspectives for therapeutic application, when lymphoma cells, possessing a high density of either spontaneous or drug-mediated transplantation antigen(s), cross the blood-brain barrier and invade the brain compartment.

Combined Treatments With Vitamin A and 5-Fluorouracil and the Growth of Allotransplantable and Syngeneic Tumors in Mice[1,2,3]

Yoshifumi Tomita,[4] Kunisuke Himeno,[5] Kikuo Nomoto,[5] Hideya Endo,[6] *and* Tomio Hirohata[4,7]

ABSTRACT—The combined effect of retinol palmitate (RP) and 5-fluorouracil (FUra) was examined with the use of allotransplantable and syngeneic murine tumor systems. The ip combined administration of RP (5,000 IU/kg/day) and FUra (5 mg/kg/day, 20 mg/kg/day, or 20 mg/kg/every 3d day) suppressed the tumor growth in ICR/JCL mice given sc inoculations of 5×10^6 allotransplantable sarcoma 180 cells and prolonged the survival time of mice inoculated ip with 10^7 tumor cells, as compared with the survival time of mice given the single administration of either RP or FUra. Similar results were obtained when BALB/c mice were inoculated sc with a syngeneic BALB/c Meth A fibrosarcoma and treated with RP (5,000 IU/kg/day) and FUra (20 mg/kg/every 3d day). The growth of Meth A implanted on day 10, as a rechallenge, was significantly suppressed in the group pretreated with RP alone or both RP and FUra for 9 days from day 1. The growth of Meth 1, another syngeneic tumor of BALB/c origin, inoculated on day 10 as a rechallenge tumor was unaffected by the treatment with RP and/or FUra. An immune response to tumor-specific antigens seemed to be involved in the combined effects of these two drugs.—JNCI 1982; 68:823–827.

The combined therapy of anticancer drugs and polyenes such as vitamin A is reportedly effective for some types of human cancer (*1–3*). Animal experiments showed that the effects of anticancer drugs together with relatively high doses ($\approx10^5$–10^6 IU/kg) of vitamin A were positive (*4–8*). Similar effects were observed in in vitro experiments, and labilizing of the cell membrane by the polyenes was given as an explanation (*9–11*). However, the actual effectiveness of the combination therapy and the related mechanisms remain open to question.

We attempted to elucidate the effectiveness and the mechanism of the combined treatment of vitamin A and FUra on an allotransplantable murine tumor system and on a syngeneic murine tumor system.

MATERIALS AND METHODS

Animals.—Female mice of a noninbred ICR/JCL stock and a BALB/c strain from CLEA Japan Inc. (Tokyo, Japan) and Shizuoka Laboratory Animal Center (Shizuoka, Japan), respectively, were kept on the basal diet CE-II (CLEA Japan Inc.) and used for experiments when they had reached 8 weeks of age.

Tumors.—Allotransplantable S180 was maintained by weekly passage in the peritoneal cavities of ICR mice. Fibrosarcomas of BALB/c origin, Meth A and Meth 1, were maintained also by peritoneal passage in BALB/c mice. After being washed with Hanks' balanced salt solution, the tumor cells harvested at 5–7 days after implantation were used for the experiments.

Drugs.—Chocola-A (RP) purchased from Eisai Co. (Tokyo) was used as vitamin A. FUra was obtained from Kyowa Hakko Kogyo Co. (Tokyo). RP and FUra were dissolved in phosphate-buffered saline (0.8% NaCl–0.02% KCl–0.11% Na_2HPO_4–0.02% KH_2PO_4) and a 5% glucose solution, respectively, before injection (0.2 ml/mouse).

Assay of antitumor activity in vivo.—ICR mice were inoculated ip with 10^7 S180 cells (for the ascites form) or sc with 5×10^6 S180 cells (for the solid form). BALB/c mice were inoculated sc with 10^7 Meth A cells. These mice were given ip various doses of RP and/or FUra from day 1 after the tumor implantation. The controls were given solvents only. Each group included 10 mice. The day of tumor inoculation was referred to as day 0, unless otherwise stated in the text. Antitumor activity of the drugs was evaluated according to tumor growth for the solid type and survival time for the ascites type.

Assay for the growth of rechallenged tumors in a syngeneic tumor system.—BALB/c mice were inoculated sc in the dorsum with 10^7 cells of Meth A on day 0 and thereafter were given ip RP and/or FUra until day 9. These same mice were rechallenged sc with 10^7 cells of Meth A in the right flank on day 10. For the comparison of the growth of Meth A and Meth 1 tumors, 10^7 cells of Meth 1 were rechallenged sc on day 10 in the left flank. The growth of the rechallenged tumor was measured at the day indicated in the text-figures.

RESULTS

Effect of a single administration of RP and FUra on tumor growth.—Preliminary experiments were done to determine appropriate doses of RP and FUra for the combined treat-

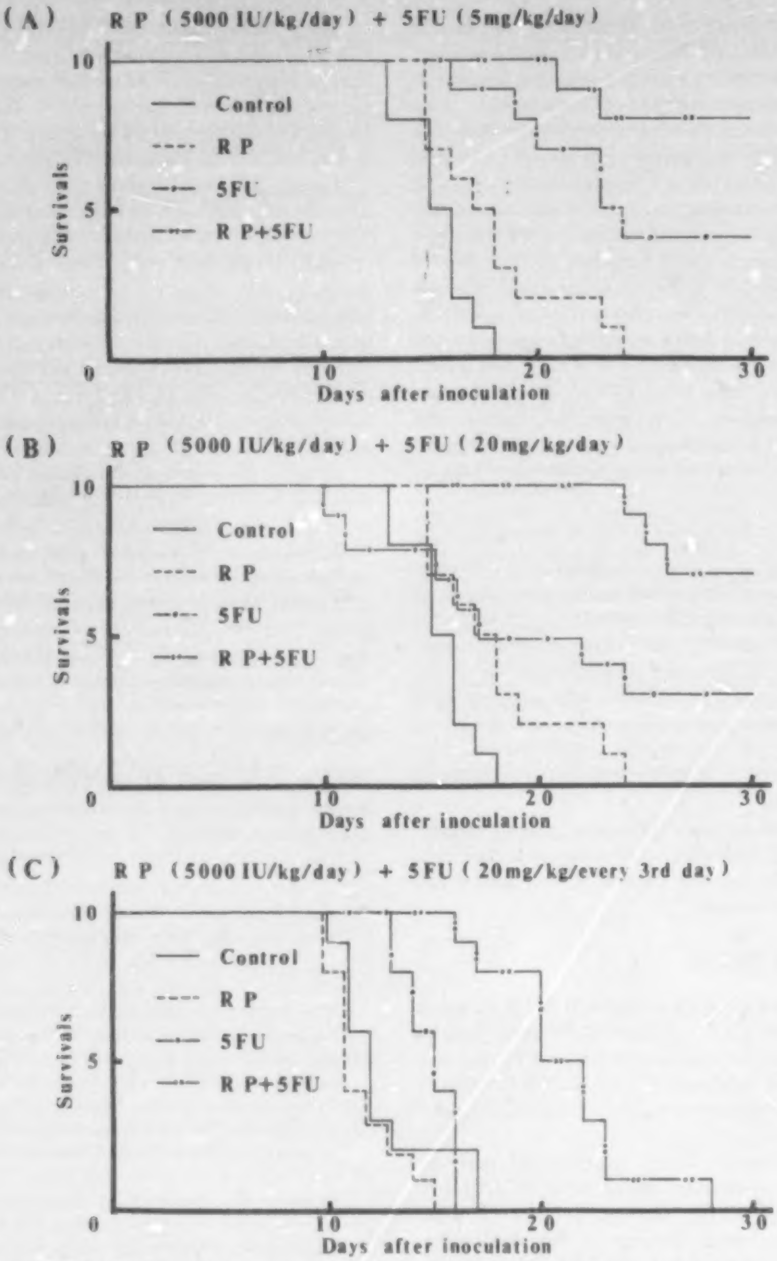
ment. The survival time and tumor growth were measured in ICR mice inoculated sc or ip with S180 cells and then given ip various doses of RP or FUra alone. The survival time of mice was not definitely altered by the RP administration of 5,000, 12,500, or 25,000 IU/kg/day. Tumors continued to grow progressively in mice treated with 5,000 IU RP/kg/day. Although administration of 25,000 or 125,000 IU RP/kg/day resulted in regression of the tumor growth after day 14, all mice in these groups died by day 20. RP in a dose of less than 5,000 IU/kg/day affected neither the survival time nor the tumor growth.

FUra administration of 5 mg/kg/day, 20 mg/kg/day, or 20 mg/kg/every 3d day prolonged the survival time of mice and to some extent suppressed the tumor growth. The lifespan of the mice was shortened when FUra at a dose of 80 mg/kg was given every 3d day.

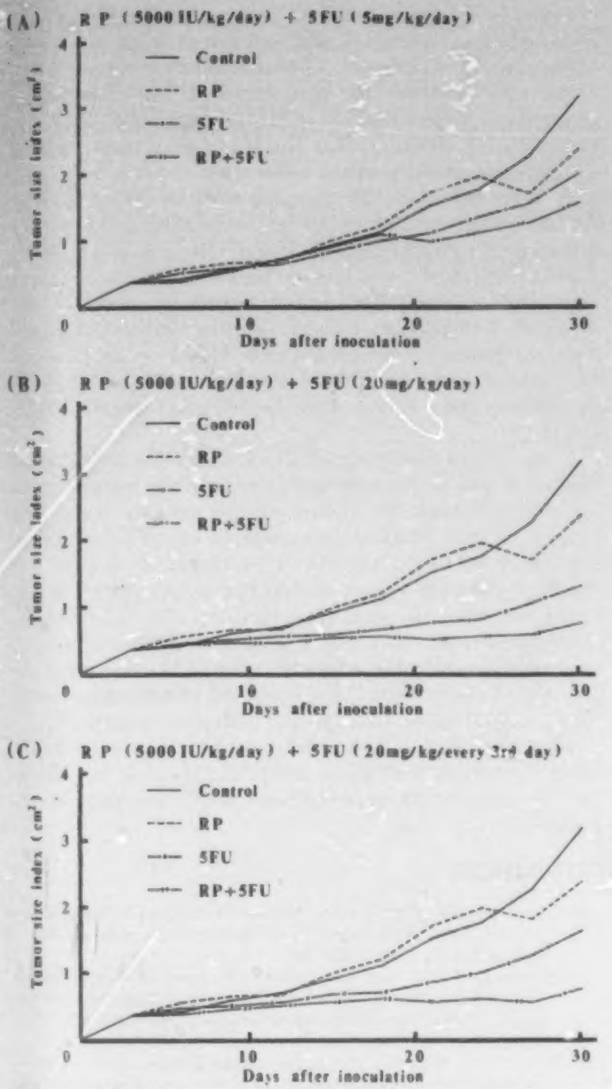


(A) RP (5000 IU/kg/day) + 5FU (5mg/kg/day)

(B) RP (5000 IU/kg/day) + 5FU (20mg/kg/day)

(C) RP (5000 IU/kg/day) + 5FU (20mg/kg/every 3rd day)

TEXT-FIGURE 1.—Combined effect of RP and FUra (5FU) on the survival time of mice inoculated with S180. ICR mice were inoculated ip with 10^7 S180 cells on day 0 and then ip with (A) 5,000 IU RP/kg/day and 5 mg FUra/kg/day, (B) 5,000 IU RP/kg/day and 20 mg FUra/kg/day, or (C) 5,000 IU RP/kg/day and 20 mg FUra/kg/every 3d day from day 1.



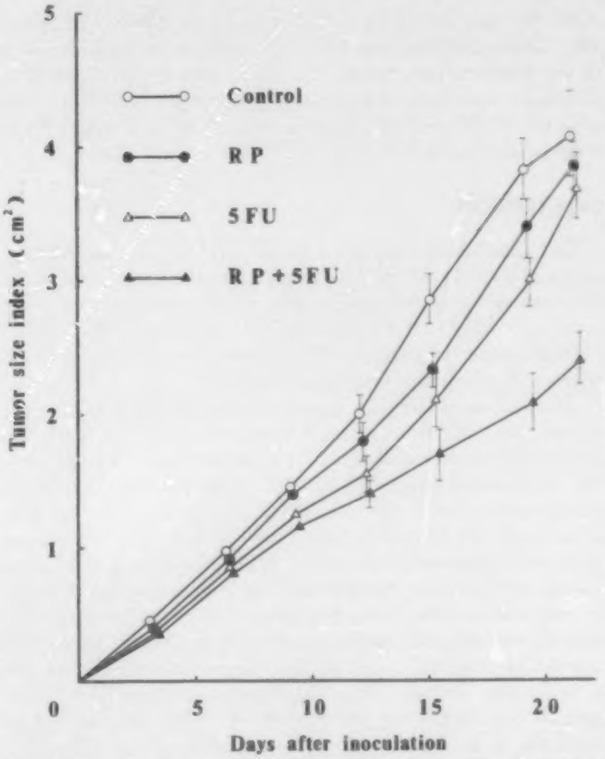
TEXT-FIGURE 2.—Combined effect of RP and FUra (5FU) on the growth of allotransplantable S180. ICR mice were inoculated sc with 5×10^6 S180 cells on day 0 and treated as stated in the legend of text-fig. 1.

A similar relation between the dose of RP or FUra and their effect on the survival time and the tumor growth was observed in BALB/c mice inoculated with the syngeneic Meth A tumor. Therefore, doses of 5,000 IU RP/kg/day and 5 mg FUra/kg/day, 20 mg FUra/kg/day, or 20 mg FUra/kg/every 3d day were used for the following experiment.

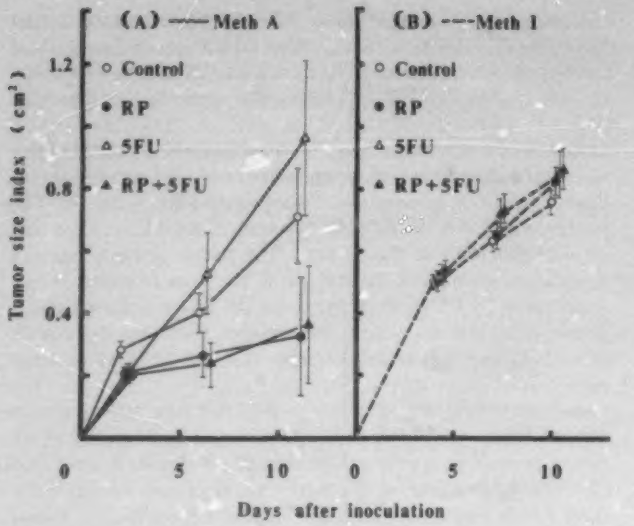
Combined treatment in an allotransplantable S180 system.—ICR mice were inoculated ip or sc with S180 cells on day 0 and then were given RP and/or FUra from day 1. The survival time of mice was prolonged with both FUra alone and the combined treatment. The combined treatment was significantly superior to treatment with FUra alone in every protocol tested (text-fig. 1). The tumor growth was suppressed most effectively with the combined treatment, particularly at 2 weeks or later after tumor transplantation (text-fig. 2). The enhancing effect of RP on the antitumor activity of FUra was clearly shown in the protocol of 5,000 IU RP/kg/day and 20 mg FUra/kg/every 3d day (text-fig. 2C).

Combined treatment in a syngeneic tumor system.—BALB/c mice were inoculated sc with syngeneic Meth A tumor cells on day 0, and the ip treatment was started from day 1. The protocol of 5,000 IU RP/kg/day and 20 mg FUra/kg/every 3d day was used in this system. The tumor growth was not significantly affected by RP alone but was to some extent suppressed by FUra alone (text-fig. 3). The combined treatment exhibited a definite suppressive effect on the tumor growth. The suppression became distinct 12 days or later after tumor inoculation.

Growth of rechallenged tumors in BALB/c mice pretreated with RP and FUra.—BALB/c mice were inoculated sc with Meth A tumor cells as a primary challenge on day 0, given 5,000 IU RP/kg/day and/or 20 mg FUra/kg/every 3d day from days 1 to 9, and transplanted with Meth A or Meth 1 tumor cells as the rechallenge on day 10. The growth of the rechallenged Meth A tumor was enhanced with FUra alone, while it was suppressed by treatment with RP alone or a combined treatment with these drugs (text-fig. 4A). The growth of Meth 1, another syngeneic tumor of BALB/c origin, as a rechallenge was not influenced by the treatment



TEXT-FIGURE 3.—Effects of RP and FUra (5FU) given concomitantly on the growth of a syngeneic Meth A tumor. BALB/c mice were implanted sc with 10^7 Meth A cells on day 0 and given ip 5,000 IU RP/kg/day and 20 mg FUra/kg/every 3d day from day 1. *Vertical bars* show standard errors of the means.



TEXT-FIGURE 4.—Suppression of the growth of syngeneic tumors given as a rechallenge in BALB/c mice pretreated with RP and FUra (5FU). BALB/c mice implanted sc with Meth A were given RP and FUra ip in a procedure similar to that described in the legend of text-fig. 3, except that the administration was continued until day 9. The mice were rechallenged with 10^7 cells of (A) Meth A or (B) Meth 1 on day 10. *Vertical bars* show standard errors of the means.

with RP and/or FUra in Meth A-primed hosts (text-fig. 4B). These findings remained the same even with excision of the primary inoculated tumors on day 9. No significant difference was observed between Meth A and Meth 1 in the growth of the rechallenged tumor when unprimed mice were treated with RP and/or FUra.

DISCUSSION

The combined treatment of RP and FUra was demonstrated to be more effective than a single administration of FUra alone in allotransplantable and syngeneic tumor systems (text-figs. 1–3). Thus a relatively low dose of RP (5×10^3 IU/kg) seems to enhance the antitumor activity of FUra when it is administered simultaneously.

The system of BALB/c mice as a host, Meth A as a target tumor, and Meth 1 as a TSA-uncross tumor of BALB/c origin was thus assumed to be a useful tool for analyzing the mechanism responsible for the combined effects of these compounds. The combined effect of anticancer drugs and vitamin A may be partly due to the adjuvanticity of vitamin A (*12–15*). Dennert and Lotan (*16*), Dennert et al. (*17*), and Glaser and Lotan (*18*) reported that the generation of killer T-cells was enhanced by treatment with vitamin A in allogeneic or syngeneic tumor systems. In the present study, RP augmented the resistance against the rechallenged tumor in a syngeneic system. This augmentation appeared to be specific for TSA, since the growth of a TSA-uncross tumor with the rechallenge was not suppressed by the RP treatment (text-fig. 4). The enhanced immune response to TSA with RP may play some role in the antitumor effect of the combined treatment. The extent of the immunologic contribution was not determined.

Other investigators ascribed the combined effect of polyenes including vitamin A and anticancer drugs to the labilizing activity of polyenes. The labilization of the cell membrane may facilitate the penetration of anticancer drugs into cells, as suggested from in vitro experiments (*9–11*, *19*). However, RP did not affect the viability of tumor cells in the presence of FUra in vitro (data not shown). This result is in agreement with the data reported by Akiyama et al. (*9*), who observed that either retinol or retinal but not RP enhanced the direct cytotoxic action of fusidic acid on HeLa cells in vitro. If RP was metabolized to retinol or retinal in vivo, such a direct effect would contribute to the in vivo suppression of primary tumors, together with the immunologic mechanism mentioned above. However, no direct effect seemed to be operative since the combined effect appeared later than 10 days after the first administration (text-figs. 2, 3).

In the group administered FUra alone, the rechallenged Meth A tumor grew more rapidly than in the controls (text-fig. 4A), although the growth of the primary tumor was suppressed with FUra alone compared with findings in the controls or RP alone (text-figs. 2, 3). Inasmuch as growth of another syngeneic tumor of BALB/c origin (Meth 1) was much the same in all groups (text-fig. 4B), TSA-specific nonresponsiveness but not a general immunosuppression may be induced by the administration of FUra alone in the presence of tumor cells. The combined treatment protected the host against the TSA-specific nonresponsiveness.

Thus vitamin A may be useful not only to potentiate the effect of anticancer drugs on the primary tumor but also to prevent recurrences or metastases after treatment of the primary tumor.

Comparative Tumor-Initiating Activity of Complex Mixtures From Environmental Particulate Emissions on SENCAR Mouse Skin[1,2,3,4,5]

Stephen Nesnow,[6] Larry L. Triplett,[7] *and* **Thomas J. Slaga[7,8]**

ABSTRACT—The value of the SENCAR mouse for testing tumorigenic properties of complex mixtures on mouse skin was studied. Seven complex mixtures were obtained as dichloromethane extracts of collected particulate emissions from three diesel-fueled automobiles, a heavy-duty diesel engine, a nonleaded gasoline-fueled automobile, a coke oven battery, and a roofing tar pot. These emissions were applied topically at multiple doses to both male and female SENCAR mice that were subsequently promoted with 12-*O*-tetradecanoylphorbol 13-acetate. Two statistical analyses were applied to the data to rank the samples and to provide 95% confidence intervals. One analysis used tumor multiplicity data, applied them to a nonlinear Poisson model, and the second analysis used tumor incidence data and applied them to a log-probit model. Both analyses ranked the complex mixtures in similar order. Benzo[*a*]pyrene content alone could not account for all the tumorigenic activity in each complex mixture, indicating that other components also contribute to the overall tumorigenic activity.—JNCI 1982; 68:829–834.

SENCAR mice, a relatively new type of highly sensitive animals bred with the selective pressure of DMBA–TPA two-stage carcinogenesis (*3*), have demonstrated their capability in mechanistic studies of chemical carcinogens. Recent works by Slaga et al. (*4*), Iyer et al. (*5*), DiGiovanni et al. (*6*), and Hennings et al. (*7*) reveal the increased sensitivity of the SENCAR mouse to polycyclic aromatic hydrocarbons and their derivatives. To date the SENCAR mouse system has not been used extensively in the analysis of complex mixtures, although mouse skin tumorigenesis with the use of other mouse strains has been applied to the biossay of complex mixtures including cigarette smoke condensate and its components (*8–11*) and combustion emission samples from gasoline (*12–17*) and diesel engines (*18, 19*). Previous reports by Kotin et al. (*18*) and by Mittler and Nicholson (*13*) presented conflicting results on the mouse skin tumorigenicity of diesel exhaust components. Similar studies with gasoline exhaust revealed a positive tumorigenic response from applications of condensates and extracts to mouse skin (*12–17*). Some of these studies used exhaust condensates, which combined the volatile and particulate phases of the emission samples, and most studies used different strains of mice. The purpose of this study was to compare tumorigenic effects of organic substances associated with the particulate phase of emission samples with the use of the same mouse stock (SENCAR) and by means of similar collection and chemical isolation procedures for all samples. A variety of sources was examined including diesel and gasoline vehicle emissions and roofing tar and coke oven emissions.

The results indicate that this mouse stock is particularly well suited for the analysis of complex environmental mixtures in addition to its demonstrated capability with pure agents.

MATERIALS AND METHODS

Sample generation and isolation.—The sample generation, isolation, and characterization have been previously described by Huisingh et al. (*20*). Diesel sample A was obtained from a preproduction 1973 Datsun-Nissan 220C vehicle; diesel sample B, from a 1978 Oldsmobile 350 vehicle; diesel sample C, from a prototype Volkswagen turbocharged Rabbit vehicle; diesel sample D from a 1972 heavy-duty Caterpillar 3304 engine; and gasoline sample, from a 1977 Ford Mustang II-302 vehicle, with catalyst and emission controls, with the use of unleaded gasoline. The vehicles were mounted on a chassis dynamometer with a repeated highway fuel economy cycle of 10.24 miles, an average speed of 48 miles/hour, and a running time of 12.75 minutes. The heavy-duty Caterpillar 3304 engine was mounted on an engine dynamometer at 2,200 rpm steady state with an 85-pound load. The diesel engines were fueled with the same batch of No. 2 diesel fuel. Particulate samples were collected by means of a dilution tunnel in which the hot exhaust was diluted, cooled, and filtered through Pallflex Teflon-coated Fiberglas filters. Particulate coke oven samples were col-

lected from the top of the coke oven battery at Republic Steel, Gadsden, Ala., with the use of a massive air volume sampler. Because of local wind conditions, an unknown portion of the emission sample may have been from the urban environment. The roofing tar emission sample was collected by means of a conventional tar pot with an external propane burner. Pine pitch (tar) was heated to 132–193°C, and particulate emissions were collected with the use of a 1.8-m stack extension and Teflon socks in a baghouse.

The diesel, gasoline, coke oven, and roofing tar emission samples were Soxhlet extracted with dichloromethane, which was then removed by evaporation under dry nitrogen. The BP analysis was performed according to the method of Swanson et al. (*21*).

Animals.—The SENCAR mouse stock, selected for its increased sensitivity to carcinogenesis (*3*), was used. These mice were derived by breeding Charles River CD-1 mice with male skin tumor-sensitive mice that were originally derived from Rockland mice. Mice were selected for sensitivity to the DMBA-TPA two-stage system of tumorigenesis for eight generations. These mice were initially obtained from Dr. R. Boutwell (McArdle Laboratory for Cancer Research, University of Wisconsin, Madison, Wis.) and are now raised at the Oak Ridge National Laboratory.

Chemicals.—TPA was obtained from Dr. P. Borchert (University of Minnesota, Minneapolis, Minn.), and BP was obtained from Aldrich Chemical Co. (Milwaukee, Wis.) All the agents were prepared under yellow light immediately before use.

Tumor experiments.—Studies used eighty 7- to 9-week-old mice per treatment group (40 of each sex). Animals were housed in plastic cages (10/cage) with hardwood chip bedding, fed Purina Laboratory Chow and water ad libitum, and maintained at 22–23°C with 10 changes of air per hour. Animals were treated and housed under yellow light for the complete experiment. All mice were shaved with surgical clippers 2 days before the initial treatment, and only those mice in the resting phase of the hair cycle were used. All samples at all doses were applied as a single topical treatment, in 0.2 ml of spectral quality acetone except for the 10-mg dose, which was administered in five daily doses of 2 mg. One week after treatment, the tumor promotor TPA (2.0 µg in 0.2 ml acetone) was topically administered twice weekly. Skin tumor formation was recorded weekly, and papillomas greater than 2 mm in diameter were included in the cumulative total if they persisted for 1 week or longer. Both the number of mice with tumors and the number of tumors per mouse were determined and recorded weekly. Papillomas were removed randomly for histologic verification.

Statistical analyses.—Analyses were done on tumor scorings performed 24–26 weeks after initiation. Two types of statistical analyses were performed. For tumor incidence data, a probit model was fitted with the use of log dose as the regression and with the assumption that some spontaneous tumors do occur in the TPA controls (*22*). The probit formula used is $P = \beta_0 + (1-\beta_0)\ \phi\ (\beta_1 + \beta_2 \ln x)$, where P is the probit proportion, x is the dose applied, and ϕ is the standard normal cumulative distribution function. The model parameters β_0, β_1, and β_2 were estimated from the raw data by maximum likelihood methods (*22*). The TID_{50} was then directly estimated as a function of these fitted parameters, and 95% confidence intervals were constructed with the use of the asymptotic variance of these parameter estimates.

The tumor multiplicity data at each dose for individual animals were analyzed by a nonlinear Poisson model with a background correction term (*23*): $\lambda_i = \beta_0 + e^{\beta_1 + \beta_2 \ln (x_i)}$ where λ_i is the number of papillomas per mouse, x_i is the dose, β_0 is the background activity, and β_1 and β_2 are the model parameters that jointly determine the increase in tumor multiplicity with increasing dose. Using maximum likelihood methods (*23*), we estimated the model parameters from the raw data and used them to calculate the number of excess papillomas per mouse over backgrond at a dose of 1 mg. Asymptotic 95% confidence intervals for these activities were obtained by means of the variance–covariance matrix estimated during the model-fitting process.

RESULTS

The complex mixture emission samples that were bioassayed for tumor-initiating activity were all dichloromethane extracts of particulate emissions. The collection devices differed depending on the type of emission source. The diesel and gasoline particulate samples were collected on Teflon-coated Fiberglas filters after the exhaust was cooled and diluted with ambient air. The coke oven particulate sample was collected by electrostatic precipitation, and the roofing tar sample was collected by filtration of the cooled emission through a Teflon sock.

Each particle type contained a different amount of organic extractable material (table 1) (*20*). The organic extractable material ranged from 7 to 8% for diesel sample A and coke oven to more than 99% for roofing tar, which was essentially all organic-soluble. BP content per milligram of extract also varied widely, from 0.0002 to 0.11%. BP content per milligram particle ranged from 0.4 to 889 ng BP/mg particle.

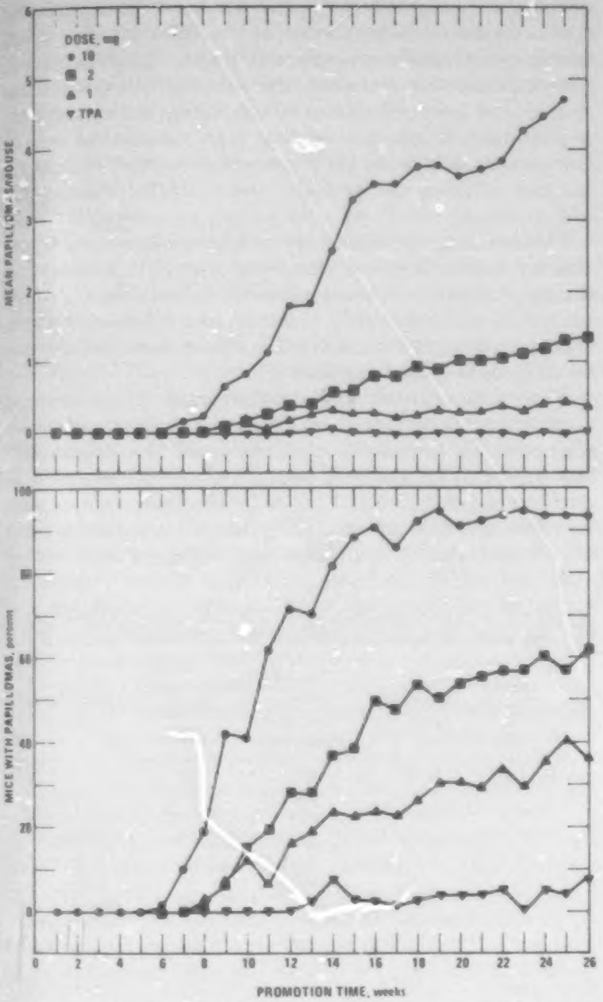
Tumor formation after application of diesel sample A began after a 7- to 8-week latent period and reached a plateau at approximately week 20 (text-fig. 1) for both tumor multiplicity (papillomas per mouse) and tumor incidence (percent mice with papillomas), except for the tumor incidence in the animals treated with 10 mg of extract which

TABLE 1.—*Analysis of organic extractable material in complex mixture samples*

Sample	Extractable, %[a]	BP, ng/mg extract[b]	BP, ng/mg particle[b]
Diesel A	8	1,173	96.2
Diesel B	17	2	0.4
Diesel C	18	26	4.6
Diesel D	27	2	0.5
Gasoline	43	103	44.1
Roofing tar	>99	889	889
Coke oven	7	478	31.5

[a] Material was extracted by dichloromethane with the use of a Soxhlet apparatus.

[b] BP analysis was performed according to the procedure of Swanson et al. (*21*) and has been previously reported by Huisingh et al. (*20*).



TEXT-FIGURE 1.—Tumor initiation by diesel sample A and TPA control group. TPA control animals were treated first with 0.2 ml acetone and then twice weekly with 2 μg TPA. Each group initially consisted of 40 male and 40 female SENCAR mice.

continued to increase. With BP, plateaus were reached at weeks 22–23 (text-fig. 2). In both examples, tumor formation expressed either as papillomas per mouse or percent of mice with papillomas was dependent on dose. Tumor latency also seemed to be dependent on the dose applied. At the highest dose tested, diesel sample A and BP elicited tumors in 90% or more of the animals treated.

In all experimental groups, survival was quite high, for 96% of the test groups experienced 90% or greater survival and 38% of the test groups had 100% survival (tables 2, 3). The four diesel samples ranged in activity from 0 to 5.7 papillomas/mouse (table 2). Diesel samples A and C gave a dose-related response in both papillomas per mouse and percent of mice with papillomas. Maximal response in diesel sample B was at the 2.0-mg dose with the higher dose giving a lower tumor response, this possibly a result of a toxic effect. Diesel sample D at several doses produced more tumors than did acetone and TPA treatment in controls (table 3); however, no dose response was evident. The gasoline sample, like diesel samples B and C, produced a weak response.

The roofing tar and coke oven samples produced dose-related, strong tumor responses. At the highest dose tested (10.0 mg/mouse), papillomas per mouse were 5.7–7.7 with practically every animal bearing tumors (table 3). BP elicited the greatest number of papillomas per mouse, 10.2 at approximately 1% the dose of the roofing tar or coke oven samples. Again, a clear dose response was evident at the four doses of BP tested. The formation of tumors in mice treated with acetone and promoted twice weekly with TPA was extremely low, 0.08 and 0.05 papilloma/mouse in male and female animals, respectively. Mice initiated with up to 100.92 μg of BP followed by promotion with acetone did not develop tumors (data not shown).

DISCUSSION

The results presented confirm and expand the earlier observations of Kotin et al. (*18*) on diesel exhaust components and clearly indicate the tumorigenic potential of these

[a] Each test group initially consisted of 40 male or female mice. Scoring of tumor data was performed 24–26 wk after initiation.

[b] Values are means ± SD for replicate samples of papillomas per mouse based on individual animal determinations. Number of replicates is the corresponding number of mice surviving for that test group.

materials. The four diesel samples varied widely in the tumorigenic responses they produced. Since the fuel, driving cycle, and collection and extraction procedures used in the production of the light-duty diesel samples A–C were similar, the differences in tumor responses are most likely because of differences in engine design and operating characteristics. It is not unlikely that different gasoline samples would also give a range of tumor responses had they been evaluated. Thus comparisons can be made only on a sample-by-sample basis, and conclusions cannot be generalized to encompass one entire class of technology. Three different types of emission sources were used in this study. The diesel and gasoline samples are collected from combustion sources, whereas coke oven emissions are from the pyrolytic conversion of coal and roofing tar emissions from the evaporation of pine pitch. It has been recently reported that the volatile components of roofing tar pitches from asphalt or coal tar are also carcinogenic on CD-1 and C3H/HeJ mouse skin (*24*).

The complex mixture samples seem to segregate into two activity classes of mouse skin "tumorigens": *a*) those producing maximal responses of greater than 5 papillomas/mouse (diesel sample A, roofing tar, and coke oven) and *b*) those producing responses of 0.2–0.5 papillomas/mouse (diesel samples B–D and gasoline).

The tumor multiplicity data were analyzed by means of a nonlinear model based on the Poisson distribution with correction for the background response. This model gave excess (over TPA control) tumor multiplicity activities in papillomas per mouse at 1 mg of extract, a convenient term for comparison of samples. The predicted activities at 1 mg of extract (table 4) correlated well with the observed re-

[a] Each test group initially consisted of 40 male or 40 female mice. Scoring of tumor data was performed 24–26 wk after initiation.

[b] Values are means ± SD for replicate samples of papillomas per mouse based on individual animal determinations. Number of replicates is the corresponding number of mice surviving for that test group.

[c] TPA-treated mice received 0.2 ml of actone and 1 wk later began a treatment schedule of 2 μg TPA two times weekly.

sponse at that dose (tables 2, 3) for those samples in which the calculated model adequately fit the observed data. With the use of this method for comparison, the complex mixture samples ranked in the order: coke oven>diesel A≧roofing tar≧diesel C = gasoline. Other distribution models (e.g., negative binomial) have also been successfully applied to the analysis of tumor multiplicity data from mouse skin experiments (*25*).

A comparison of the samples by tumor incidence was performed by means of the log-probit model with a nonzero background (*22*), and the results are described in table 5. The log-probit model considers mice on an individual basis and groups them into 1) mice with no tumors and 2) mice with 1 or more tumors. The samples are ranked by the calculated TID_{50}. All samples except diesel sample B, diesel sample D, and gasoline had data that spanned the 50% tumor incidence value; therefore, log-probit calculations for these samples reflect the observed tumor incidences. The calculated results show that the BP treatment is more active than, and statistically different ($P=0.05$) from, the coke oven, which is more active than, and statistically different from, diesel sample A or roofing tar. (These samples are statistically equivalent.) When subjected to the log-probit analysis, diesel samples B–D and the gasoline sample gave TID_{50} values much greater than 10 mg with wide 95% confidence intervals.

Both the tumor multiplicity and tumor incidence data gave similar rankings for the most active samples, even though different statistical models were used in their analyses.

Mouse skin has been reported to be quite sensitive to the tumorigenic effects of polycyclic aromatic hydrocarbons (*3–7*). The SENCAR mouse is exquisitely sensitive to BP as a tumor initiator because 4–9 μg applied once and followed by twice weekly applications of 2 μg TPA will produce a 50% papilloma incidence, depending on sex (tables 3, 5). However, the tumor data presented in tables 2 and 3 cannot be explained solely by the BP content (*see* table 1), because there is no significant relationship between TID_{50} (or mean papillomas per mouse) and BP content in each complex mixture. The coke oven sample produced 2.0–2.6 papillomas/mouse at 1 mg of extract. The BP content in 1 mg of coke oven extract is 478 ng, a dose that would produce less than 0.5 papilloma/mouse when applied to SENCAR mice. The diesel C sample contains 2 ng BP/mg extract, a dose that would produce only a background response; yet 1 mg of diesel sample C produces 0.21–0.26 papilloma/mouse. Diesel sample A contains the largest amount of BP—1,170 ng/mg of extract. Tumors obtained at the 10-mg extract dose (11.7 μg BP) level were approximately 5 or 6/mouse. Similar doses of BP (12.62 μg) produced only 1 or 2 tumors/mouse. Therefore, BP can be accounting for only 20–30% of the activity seen, and other components of the mixture seem to be playing a role in its tumorigenic activity. For example, β-propiolactone, a mouse skin tumorigen (*26*), has been detected in diesel exhaust particulate samples (*27*). Cocarcinogenic effects may also play a role in the overall activity.

TABLE 4.—*Comparison of predicted tumor multiplicity based on a nonlinear Poisson model*[a]

Sample	Excess papillomas per mouse at 1 mg of extract	Sex of mice	95% confidence intervals
Coke oven	2.2[b]	♂	2.0–2.4
	2.0[b]	♀	1.9–2.2
Diesel A	0.49[b]	♂	0.38–0.63
	0.68[b]	♀	0.57–0.79
Roofing tar	0.38[b]	♂	0.30–0.49
	0.44[b]	♀	0.35–0.55
Diesel C	0.21	♂	0.14–0.3
	0.17	♀	0.11–0.25
Gasoline	0.17	♂	0.12–0.24

[a] Predicted excess (over TPA controls) papillomas per mouse at 1 mg of extract were calculated on a UNIVAC 1100 computer with the use of the nonlinear Poisson model as described in "Materials and Methods." Calculations are shown only for those experimental groups for which the calculated model adequately fits the observed data at all dose levels.

[b] The distribution of tumors at some dose levels was not Poisson because the variances exceeded the means.

TABLE 5.—*Comparison of tumor incidence based on log-probit analysis*[a]

Sample	TID_{50}, mg[b]	Sex of mice	95% confidence intervals
BP	0.0036	♂	0.0021–0.0062
	0.0091	♀	0.0057–0.015
Coke oven	0.30	♂	0.22–0.40
	0.42	♀	0.31–0.58
Diesel A	1.6	♂	1.2–2.2
	1.5	♀	1.1–1.9
Roofing tar	1.8	♂	1.2–2.7
	2.1	♀	1.5–2.8

[a] Log-probit analysis with a nonzero background was performed according to Hasselblad et al. (*22*) on a UNIVAC 1100 computer as described in "Materials and Methods."

[b] Diesel samples B–D and gasoline produced TID_{50} values >10 mg with large 95% confidence intervals and are not listed.

The identity of substances present in these complex mixtures is currently under study and will yield important information regarding their active components. SENCAR mouse skin seems particularly well suited for evaluation of the tumorigenic potential of both pure agents or complex mixtures. The results presented here further substantiate this fact and provide information on the relative tumorigenicity based on tumor initiation of a series of complex mixtures obtained from combustion, pyrolytic, and evaporative sources.

Moloney Murine Sarcoma Virus Tumors in CBA/J Mice: Chemopreventive and Chemotherapeutic Actions of Supplemental β-Carotene[1,2,3,4]

Eli Seifter, *Ph.D.*,[5,6] **Giuseppe Rettura**, *Ph.D.*,[6] **Jacques Padawer**, *Ph.D.*,[7] *and* **Stanley M. Levenson**, *M.D.*[6]

ABSTRACT—Decreased tumor frequency, increased latent period, and increased rate of tumor regression were observed in male inbred CBA/J mice fed supplemental β-carotene before and/or after they were inoculated with the Moloney sarcoma virus. When β-carotene feeding was begun after tumors were already present, it markedly increased the rate of tumor regression. β-Carotene minimized the virus-induced thymus gland involution that accompanies tumor growth, and this action on the thymus gland was believed to underlie part of β-carotene's antitumor activity. The basal diet, a standard commercial mouse chow containing more vitamin A than the National Research Council recommends as a daily allowance for rodents, supported normal growth, reproduction, and longevity of normal mice. The work reported here is the first demonstration of the antitumor action of β-carotene in mice inoculated with an oncogenic virus.—JNCI 1982; 68:835–840.

β-Carotene, a dietary precursor of vitamin A, is currently the subject of much interest as a possible tumor preventive agent (*1*). Epidemiologic data have shown that populations with low serum vitamin A contents are at higher risk for tumor development than are those with normal or high serum vitamin A levels (*2*). This finding has led to suggestions that supplemental vitamin A might have beneficial effects in lowering tumor incidence of populations at high tumor risk. However, the possibility that prophylactic use of vitamin A could induce clinically significant vitamin A toxicity has caused workers to explore alternative vitamin A-like dietary tumor preventive agents. Recent examinations of epidemiologic data show that populations ingesting foods rich in β-carotene are at lower tumor risk than are those on a low carotene diet (*3*). Because β-carotene has minimal toxicity, the concept of using β-carotene for tumor chemoprevention is attractive. The present study[8] was done to determine whether supplemental β-carotene is effective for tumor prevention and therapy in a tumor system that is responsive to supplemental vitamin A.

MATERIALS AND METHODS

Three experiments were conducted to examine the influence of supplemental β-carotene on tumor incidence and growth due to the M-MuSV tumor virus: In the first two, supplemental β-carotene feeding was begun before tumor inoculation, whereas in the third, β-carotene supplementation was begun after the tumor had developed. A fourth experiment was done to obtain data on the influence of supplemental β-carotene on the thymic status of normal and virus-inoculated mice, because these findings might contribute to understanding the mechanisms of antitumor action of β-carotene.

Animals, housing, and diets.—Five-week-old male inbred CBA/J mice were purchased from The Jackson Laboratory, Bar Harbor, Maine, and maintained in our laboratory for 1 week before use in any experiment. Two or 3 days after their arrival in our laboratory, the animals were examined, weighed, and allocated randomly to cages housing 5 mice each. Shoe box-type cages of opaque polyethylene with the dimensions of 5×8×12 inches and with a 3-mesh galvanized wire top were used. The mice were housed in a room with a 12-hour day–night cycle, temperature of 25°C, and relative humidity of about 35%.

The powdered laboratory chow (Teklad, Inc., Monmouth, Ill.) that served as the basal or control ration for the mice contained 6,190 IU vitamin A palmitate/kg and 4.3 mg β-carotene (equivalent to 7,167 IU vitamin A)/kg; the total (13,357 IU/kg diet) is well above the National Research Council recommended daily requirement of vitamin A for normal rodents, which averages 6,000 IU/kg diet for growth, pregnancy, lactation, and longevity. Therefore, the basal control diet is *not* deficient in vitamin A. Rodents fed this diet have normal levels of serum vitamin A of 62±3 μg/dl (*4*).

Experimental diets contained additional β-carotene (90 or 120 mg/kg powdered chow). These values were chosen because 90 mg β-carotene is equivalent to 150,000 U vitamin A (IU=0.62 μg β-carotene), the level of dietary vitamin A supplementation that we used earlier and found effective against M-MuSV (*5, 6*).

M-MuSV.—The virus (M-MuSV) used in these experiments was originally obtained from Dr. J. B. Moloney,

[8] The concept presented in the present report, i.e., the use of β-carotene for tumor chemoprevention and for tumor chemotherapy, was first proposed by us in an application to the National Institutes of Health in 1974 (NIH grant application CA 16818-01, pp. 28, 38, and 40).

National Cancer Institute, and was designated as lot #206. For use as an inoculum, the virus was passed through CBA/J mice from which the tumors were harvested and treated for extraction of the virus. The virus was reconstituted with a phosphate-saline buffer so that virus recovered from 1 g of tumor was present in 1 ml of suspension, yielding 1 g eq/ml. In the present experiments, the virus was used in tenfold (10^{-1} g eq/ml) or hundredfold (10^{-2} g eq/ml) dilutions. Inoculations consisted of im injections of 0.1 ml of virus suspension in the inner aspect of the left thigh. Tumors were graded on a scale of 1–4, as described by Blumenshein and Moloney (*7*).

Lymphocyte count.—Mice were killed in an ether chamber, and thymus glands were removed and weighed to the nearest milligram on a Roller-Smith tissue balance. Derived statistics are reported to 0.1 mg.

Thymic lymphocytes were counted in samples prepared by mincing the thymus gland of each animal in 6 ml buffer (medium 199 with Hanks' salts; GIBCO, Grand Island, N.Y.); the homogenate was then passed through a No. 100 stainless steel screen. The residue was washed twice with 1.5-ml portions of buffer, and the final volume was adjusted to 10 ml. The cell suspension was mixed thoroughly, and 0.1 ml was further diluted to 2 ml with buffer. An aliquot of this suspension was then placed in a Neubauer hemacytometer (American Optical Corp., Buffalo, N.Y.), and lymphocytes were counted independently by two observers.[9]

Experiments.—Experiments on the thymotropic action of β-carotene were begun in 1974 (*8*). The experiments with virus were done in the spring of 1975 and the fall of 1977 (*9*).

Experiment 1: Four groups of CBA/J mice (10 mice/group) were established and housed as described. Two of the groups were fed the basal ration, and 2 received the basal ration supplemented with 90 mg β-carotene/kg diet. After 3 days, half the animals (1 group of controls and 1 group of β-carotene-supplemented mice) were inoculated with 0.1 ml of a virus suspension containing 0.1 eq of the virus present in 1 g tumor/ml (10^{-1} g eq/ml), and the other half were inoculated with 0.1 ml of the virus solution diluted 1:10 with buffer (10^{-2} g eq/ml).

Experiment 2: This experiment was conducted several weeks later than experiment 1. Not only was a different shipment of mice used, but the β-carotene supplements were also increased to 120 mg/kg diet. Other conditions were similar to those of experiment 1.

Experiment 3: The purpose of this experiment was to determine if supplemental β-carotene fed to mice only after M-MuSV tumors had appeared would influence tumor growth. Twenty male CBA/J mice were inoculated with 0.2 ml of a 10^{-1} g eq preparation. By day 7, these mice had a mean tumor score of 2. At this time, half the mice were started on the β-carotene-supplemented ration, while the other half were continued on the basal ration.

Experiment 4: The purpose of this experiment was to determine the effect of supplemental β-carotene on the thymus glands of normal mice and mice inoculated with M-MuSV.

Four groups of mice were established, each of which consisted of 6 mice/cage and 4 cages/group. Group 1 received the control ration and no virus inoculation; group 2 received the control ration plus M-MuSV (10^{-1} g eq/ml); group 3 was β-carotene supplemented (90 mg/kg diet) but not virus inoculated; and group 4 was β-carotene supplemented and M-MuSV inoculated (10^{-1} g eq/ml). Virus was inoculated 3 days after the mice started their respective diets. On days 1, 2, 3, 7, and 17 post inoculation, mice of one cage in each group were weighed before being killed, and their thymus glands were studied.

RESULTS

Influence of β-Carotene Supplementation on M-MuSV Tumors

Tumor incidence was reduced when mice were fed β-carotene supplements before and after their inoculation with either the higher or lower inoculum of M-MuSV ($P<0.005$ and <0.009, respectively, table 1). Supplemental β-carotene increased the latent period for tumor development for animals receiving either the higher virus inoculum ($P<0.005$ in experiment 1 and <0.01 in experiment 2) or the more dilute inoculum ($P<0.008$ in experiment 1 and <0.05 in experiment 2, table 2).

Supplemental β-carotene slowed the daily increment of tumor progression. For the higher dose inoculum, the tumor growth increments were 0.25 score U/day; β-carotene lowered these values to 0.13 U/day in experiment 1 and to 0.19 U/day in experiment 2. Similarly for the lower virus inoculum, the daily increments were lowered from 0.25 to 0.09 U/day by β-carotene in experiment 1 and from 0.19 to 0.09 U/day in experiment 2 (table 3; text-fig. 1).

When tumors developed in the β-carotene-supplemented mice, the tumors were present for a shorter time than if the mice were β-carotene unsupplemented (table 3). The shortened time resulted from lengthened latent periods and more rapid tumor regression (tables 3, 4; text-fig. 1). Mean tumor size was dependent on inoculum size; smaller inocula produced tumors of smaller mean size. Mean tumor size was reduced by β-carotene supplementation, which had an effect similar to that of reducing the inoculum size by one log unit.

Because of the large inoculum size used, tumor progression was most rapid in experiment 3, and tumor regression did not occur in control animals during the period of observation

(text-fig. 2). Tumor regression was rapid in the β-carotene-supplemented groups, and no mouse died. The experiment was concluded after regression had occurred in all of the β-carotene-supplemented mice (38 days). By that time, 3 of 10 control mice with grade 4 tumors had died between days 28 and 30.

Influence of β-Carotene Supplementation on the Thymus Glands of Normal and M-MuSV-Inoculated Mice

After 3 days of β-carotene supplementation (table 5), the size of the thymus glands increased ($P<0.001$) and the numbers of small lymphocytes in the gland increased by more than 50% ($P<0.001$). Inoculation with M-MuSV caused a rapid and progressive loss in thymus mass due to the decrease in the numbers of small thymic lymphocytes (50% in 7 days, $P<0.001$). Supplemental β-carotene largely prevented this: The decrease in these mice was 27%; this difference is statistically significant ($P<0.005$).

DISCUSSION

The experiments reported here clearly establish prophylactic and therapeutic actions of supplemental β-carotene given to CBA/J mice inoculated with M-MuSV: 1) β-Carotene supplementation begun before M-MuSV inoculation and continued throughout the experiment lowered tumor incidence, decreased tumor scores, and decreased the time required for tumor regression. 2) β-carotene supplementation begun after classification of tumors as grade 2 in mice receiving large inocula of M-MuSV hastened regression. 3) Administration of β-carotene to normal mice caused increases in thymus weights and in the numbers of small thymic lymphocytes, with no other obvious changes in the gross appearance of the thymus glands. Supplemental β-carotene begun before M-MuSV inoculation partially prevented the thymic involution that otherwise occurred in mice inoculated with M-MuSV.

Comparison of these results with those we have reported for supplemental vitamin A shows that the qualitative and quantitative anti-M-MuSV tumor activities of β-carotene

are similar to those of vitamin A. Similarly, we have found in other experiments that supplemental β-carotene, like vitamin A, inhibits the development and growth of cancer in C3H mice inoculated with syngeneic C3HBA (breast adenocarcinoma) cells (*9*).

Spontaneous resistance of M-MuSV in syngeneic BALB/c mice is strongly dependent on lymphocytes, particularly on T-lymphocyte activity (*10*). Similarly, work from our laboratory has shown that resistance to M-MuSV tumor growth in CBA/J mice is strongly decreased by agents or conditions that inhibit lymphocyte activity, such as antilymphocytic serum, thymectomy, cortisone or ACTH administration, or burns or other physical stress, whereas resistance is increased greatly by thymic hormones, vitamin A, or other agents that induce lymphopoiesis or prevent injury-induced lymphopenia (*11–13*).

Along with the increase in thymus cellularity, Cohen and Cohen (*14*) have shown the development in vitamin A-supplemented mice inoculated with sheep red blood cells of an increase in the number of splenic antibody-producing cells. Not only Floershein and Bollag (*15*), but also Rettura et al. (*16*) have shown that supplemental vitamin A speeds the rejection of skin allografts by mice.

We have called those actions of vitamin A that increase the numbers of thymus gland lymphocytes and the numbers of circulating lymphocytes the thymotropic and lympho-

poietic actions of supplemental vitamin A (*17–19*). We have correlated these actions of supplemental vitamin A with the development of increased immune competence, particularly of cell-mediated reactions such as those that accompany skin rejection (*16*), immunization to poxvirus vaccine (*20*), or regression of M-MuSV tumors and decreased rates of tumor take when transplanted tumor inocula are from nonviral, immunogenic tumors (*21*). Similarly, we have found that β-carotene supplementation promotes allograft rejection (*22*) and induces a modest increase in peripheral blood lymphocytes (*23, 24*).

We have called the thymic involution which occurs after M-MuSV inoculation a stressful action of the virus because it resembles the thymic involution reported to occur after a large number of physical, chemical, or pathogenic stressors have been applied (*25*). We have reported that supplemental vitamin A moderates the thymic effects of these stressors and have referred to this response as the anti-stress action of vitamin A (*26*). In the present study it is clear that β-carotene is also an antistress (antitumor) agent, thus extending our findings regarding the influence of β-carotene in suppressing stress responses in physically injured or chemically poisoned rodents.

Cohen et al. (*27*) have shown that elective operation trauma (general anesthesia) induces relative lymphopenia and diminished lymphocyte transformation (in vitro). These inhibitions of immune phenomena were prevented when dietary vitamin A supplements were fed to patients and are thus related to our findings in rodents.

Recently, Medawar and Hunt (*28*) have pointed out that the immunity-promoting action of vitamin A is probably through its actions on the cellularity of thymus glands and that this action is probably critical for the antitumor action of the vitamin. This view (*28*) is similar to the one we have expressed earlier (*5, 17, 29–31*). Similarly, Lotan and Dennert (*32*) and Lotan (*33*) have related the thymic effects of vitamin A to the enhancement of the tumor immunity by vitamin A.

The data do not permit us to determine if the actions of β-carotene reported here require that it be converted to vitamin A; the experiments were not designed to adduce this specific point. The important effects of β-carotene which we have described as shown by the thymus, the white blood cells, and the control of the tumor growth are produced by amounts of β-carotene that do not, in our experience, lead to any signs of vitamin A toxicity. We speculate that, as a consequence of their concentration in certain organs, tissues, and body fluids other than blood plasma, such as lymph (*34*), vitamin A and β-carotene influence the growth and maturation of cells that regulate various immune functions, such as thymus function, and thereby moderate tumor growth.

Nonimmunogenic Radiation-Induced Lymphoma: Immunity Induction by a Somatic Cell Hybrid[1,2,3]

Eitan Yefenof,[4] Mira Goldapfel,[4] *and* Rosalie Ber[5]

ABSTRACT—The cell line designated PIR-2 is a nonimmunogenic X-ray-induced thymoma of C57BL/6 origin that is unable to induce antitumor immunity in syngeneic lymphocytes in vitro and in mice in vivo. Fusion of PIR-2 with an allogeneic "universal fuser" A9HT (clone 3c) resulted in the establishment of a somatic cell hybrid designated A9/PIR. C57BL/6 lymphocytes sensitized in vitro with A9/PIR could lyse parental PIR-2 cells, as well as other syngeneic tumors. However, immunization of mice with the hybrid significantly enhanced PIR-2 tumor takes while it partially protected the animals against a challenge with unrelated syngeneic tumors. The results imply that somatic cell hybridization can increase the immunogenicity of an otherwise nonimmunogenic tumor. However, in view of the enhancing effects of hybrid preimmunization on parental tumor cell growth, the possible application of this approach for immunotherapy is questionable.—JNCI 1982; 68: 841–849.

Adult C57BL/6 mice exposed to fractionated irradiation or inoculated intrathymically with RadLV develop a high incidence of lymphatic leukemias after a latent period of 3–6 months (*1*). Previous studies in our laboratory have demonstrated that RadLV-induced thymomas may elicit syngeneic antitumor cell-mediated immunity in vitro, which is induced by and is directed at virus-associated antigens expressed on the tumor cell membrane (*2, 3*). In contrast, X-ray-induced primary thymomas do not express virus-related antigenicity and are not immunogenic in vitro.

Since it has recently been reported that rejection of a nonimmunogenic murine lymphoma could be induced by immunization with somatic cell hybrids (*4*), we decided to investigate whether host immune unresponsiveness toward X-ray-induced tumors could be overcome after immunization with a hybrid between a radiogenic leukemia and an allogeneic cell.

MATERIALS AND METHODS

Animals.—Female inbred C57BL/6 mice 5–6 weeks old at the start of the experiments were used. The mice were obtained from the animal facilities of the Hebrew University-Hadassah Medical Center, Jerusalem.

Antisera.—Anti-H-2^b and anti-H-2^k alloantisera were produced by immunizing BALB/c mice with pooled spleen, kidney, and liver cell suspensions from C57BL/6 and C3H mice, respectively, at biweekly intervals over 20 weeks. Rat anti-RadLV was the gift of Dr. M. Haas, Salk Institute, La Jolla, Calif., and was prepared as described earlier (*5*). Goat anti-Rauscher gp70 and anti-p30 antibodies were provided by Dr. E. M. Fenyo, Karolinska Institute, Stockholm, and were prepared as described elsewhere (*6*). Anti-Thy 1.2 monoclonal antibody was the gift of Dr. P. Lake, University College, London, and was prepared as described in (*7*).

Cell lines.—EL-4 is a 7,12-dimethylbenz[*a*]anthracene-induced T-cell lymphoma of C57BL/6 origin (*8*), 136.5 is a RadLV-induced C57BL/6 thymoma (*9*), YBA is a Moloney virus-induced T-cell lymphoma of CBA (*H-2^k*) origin (*4*), and PIR-2 is a cell line established in our laboratory from an X-ray-induced C57BL/6 thymoma. PIR-2 cells survive perfectly in a medium supplemented with HAT but expire within 24–48 hours when subjected to 100 μ*M* ouabain. The cell lines were grown in RPMI-1640 medium containing 10% FCS and antibiotics. A9HT (clone 3c) is a "universal fuser" derived from L-cells of C3H (*H-2^k*) origin. The isolation of this double mutant cell line, containing both dominant and recessive mutations, has been described elsewhere (*10*). The cells were routinely cultivated as monolayer cultures in DMEM supplemented with 7% FCS. To minimize reversion, we routinely added 50 μg 6-thioguanine/ml and 3 m*M* ouabain to the medium. A9HT cells cannot survive in medium containing HAT.

Fusion and selection of hybrids.—A subconfluent monolayer of A9HT cells in a 250-ml flask was rinsed twice with cold, serum-free, alkaline RPMI-1640, after which 1,000 hemagglutinating units of UV light-inactivated Sendai virus in 2 ml PBS was added and absorbed on ice for 30 minutes.

Twice-rinsed PIR-2 cells, (10^7) in 0.5 ml PBS were added to the monolayer. The flask was left on ice for 30 minutes and then transferred to 37°C for 60 minutes, when 20 ml DMEM supplemented with 10% FCS was added. The growth medium was supplemented with HAT-O 24 hours later.

Most of the cells expired within 72 hours, but a few survivors began to multiply after 7–10 days, and 3 weeks later these cells grew into colonies. The mass hybrid culture designated A9/PIR was not cloned. The cells grew as an easily detachable monolayer, which could be subcultured without trypsinization.

Chromosome analysis.—Cells in exponential phase were in-

cubated with 0.3 μg Colcemid/ml (GIBCO, Grand Island, N.Y.) for 1 hour at 37°C, resuspended in a hypotonic 0.075-*M* potassium chloride solution for 20 minutes, and fixed in freshly prepared methanol:acetic acid 3:1 solution. Metaphase spreads were prepared by dropping the solution on chilled wet slides and staining with Giemsa (Fisher Scientific Co., Fair Lawn, N. J.) diluted 1:15 in 0.15 *M* phosphate buffer (pH 8.0). Metaphases were examined by high-power light microscopy, and the modal number of biarmed and total chromosomes was calculated on the basis of 10–20 metaphases.

Complement-dependent microcytotoxicity assay.—With the use of an automatic Hamilton syringe, aliquots of 3-μl antiserum dilutions containing 10^3 target cells were placed into rings of a microtray (Hamax, Moss, Norway) covered with paraffin oil. After 20 minutes of incubation at 4°C, 1 μl of rabbit C′ diluted 1:6 was added to each ring, and the trays were incubated for another 45 minutes at 37°C. Subsequently, 1 μl of 0.4% trypan blue was added to each ring, and the proportion of living cells was determined under the light microscope. CI was calculated according to the formula: CI=% living cells in control−% living cells in test sample/% living cells in control.

Immunization.—Tumor cells (30×10^6) in a total volume of 0.2 ml, irradiated with 9,000 rad, were inoculated sc to both flanks of C57BL/6 mice.

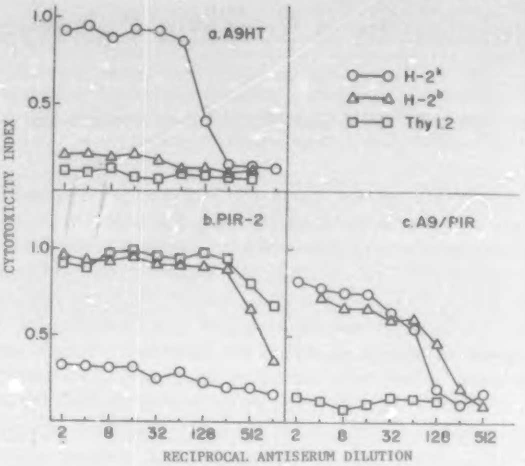
Tumor cell challenge.—Various numbers of viable tumor cells were inoculated sc into control or preimmunized C57BL/6 mice 2 weeks after immunization.

MLTC.—Splenocytes from normal animals or animals that were preimmunized (primed) 10–14 days earlier were mixed in tissue culture flasks with irradiated (9,000 rad) tumor cells at a 10:1 responder:stimulator ratio under conditions described elsewhere (*11*). Mixed cultures were incubated for 6 days in a humidified atmosphere with 5% CO_2 at 37°C.

Lymphocyte mediated cytotoxicity assay.—Following 6 days of incubation, mixed cultures were harvested and their cytotoxic activity was determined with the use of the 5-hour incubation $Na_2{}^{51}CrO_4$ release assay as described elsewhere (*12*). Percentage ^{51}Cr SR was calculated according to the formula: SR%=(release in test−spontaneous release/maximal release−spontaneous release)×100.

RESULTS

Chromosome analysis of parental and hybrid cell lines.—Typical metaphase plates of PIR-2, A9HT, and A9/PIR are shown in figures 1, 2, and 3, and the results obtained with 10–20 different metaphases of each line are summarized in table 1. The modal chromosome number of A9HT was 51 (range 45–57) with a mean of 22 biarmed chromosomes which served as markers for this cell line. Ten metaphases of PIR-2 showed 41 acrocentric chromosomes apparently due to a trisomy in chromosome 15, which is a common feature of murine T-cell lymphomas (*13*). A9/PIR had a mode of 82 chromosomes of which 21 were biarmed.



TEXT-FIGURE 1.—Expression of H-2 and Thy 1.2 alloantigens on parental and hybrid cells determined by C′-dependent microcytotoxicity assay. The initial antiserum dilutions were: anti-H-2^b, 1:10; anti-Thy 1.2, 1:1,000.

Membrane characteristics of parental and hybrid cell lines.—A9HT and PIR-2 expressed the *H-2^k* and *H-2^b* haplotypes, respectively (text-fig 1). PIR-2 expressed the T-cell marker Thy 1.2 as well. Both *H-2^k* and *H-2^b* were expressed on the A9/PIR hybrid, whereas Thy 1.2 was not expressed. PIR-2 did not express virus-associated antigens on the cell membrane (text-fig. 2), whereas A9HT reacted with anti-gp70, p30, and RadLV antisera. The expression of virus-associated antigens was retained in the A9/PIR hybrid (text-fig. 2). The characteristics of the hybrid compared with those of the parental cell lines are summarized in table 1.

Inhibition of tumor growth in preimmunized recipients.—All C57BL/6 animals (5 of 5) developed tumors and subsequently succumbed when inoculated with 10^5 EL-4, 136.5, or PIR-2 cells (table 2). PIR-2 tumor growth was somewhat delayed when compared to EL-4 and 136.5 tumor growth; palpable tumors appeared later and the mice survived longer.

C57BL/6 mice could be partially protected against a challenge of 10^5 EL-4 or 136.5 cells if they were preimmunized with either EL-4 or 136.5 (table 2). Under such circumstances some of the animals remained tumor-free,

and tumor takes in the rest were significantly delayed. However, mice preimmunized with EL-4 or 136.5 were not protected against a challenge with PIR-2 cells. Immunization with PIR-2 cells did not inhibit tumor growth after challenge with either EL-4, 136.5, or PIR-2 itself.

Effect of irradiation on tumor takes.—EL-4 tumor growth was significantly enhanced in C57BL/6 animals that had been exposed to 400 rad whole-body irradiation 24 hours before challenge (table 3). Preirradiation of PIR-2 recipients had no effect on tumor appearance or survival.

Generation of antitumor cytotoxicity in vitro.—We have previously shown (*2*) that generation of cytotoxicity in C57BL/6 lymphocytes responding to syngeneic RadLV-induced tumors is dependent on preimmunization of the responder cell donor with the appropriate tumor cells. In vitro sensitization of C57BL/6 splenocytes with either 136.5 or EL-4 cells after in vivo priming resulted in the generation of cytotoxicity

TEXT-FIGURE 5.—Cytotoxic activity of C57BL/6 lymphocytes stimulated in vitro with parental and hybrid cell lines.

toward the corresponding tumor line (text-fig. 3). In contrast, lymphocytes primed and sensitized by PIR-2 cells showed no antitumor cytotoxic activity.

Lymphocytes that were 136.5 primed became cytotoxic when sensitized in vitro with either 136.5 or EL-4 cells (text-fig. 4). Both 136.5 and EL-4 targets, but not PIR-2 targets, were susceptible to lysis by cytotoxic cells obtained from in vitro stimulation with either 136.5 or EL-4 cells. When splenocytes of 136.5-primed animals were cocultivated with PIR-2 cells, they showed no cytotoxic activity toward PIR-2, 136.5, or EL-4.

Text-figure 5 shows the cytotoxic activity of C57BL/6 lymphocytes cocultivated with the A9/PIR hybrid or parental lines. Lymphocytes stimulated by A9/PIR could efficiently lyse PIR-2 as well as EL-4 targets. Considerable cytotoxic activity was also observed against YBA cells which share the *H-2*^{k} haplotype with A9HT. C57BL/6 splenocytes sensitized by A9HT cells were cytotoxic toward YBA targets but not to EL-4 or PIR-2 targets. Sensitization with PIR-2 or with a mixture of PIR-2 and A9HT cells did not result in generation of cytotoxicity.

Effect of immunization with A9/PIR on tumor growth.—All control C57BL/6 animals (100%) developed tumors and subsequently died when inoculated sc with either 10^4, 10^5, 10^6 EL-4 cells (table 4, text-fig. 6). When the mice were preimmunized with A9/PIR cells, a partial protection against EL-4 tumor growth was observed; some animals remained tumor-free, and in the rest tumor development and death were significantly delayed. Preimmunization with A9HT, PIR-2, or a mixture of A9HT and PIR-2 cells was not protective. Similar results were obtained with C57BL/6 animals challenged with 136.5 cells (results not shown).

However, A9/PIR preimmunized mice inoculated with PIR-2 cells showed enhancement of tumor growth and animal death (table 5, text-fig. 7). The enhancing effect was significant when 10^5 and 10^6 PIR-2 cells were inoculated, whereas tumors in A9/PIR immunized animals challenged with 10^4 or 10^7 cells did not develop faster than tumors in control mice. The protective effect against EL-4 and the

DISCUSSION

The demonstration that many experimental tumors can elicit immune responses in syngeneic hosts raised the possibility of immunologic intervention in the process of neoplasia (*14, 15*). The relevance of this approach, however, had been disputed in view of recent studies that suggest that spontaneously arising tumors are, in most cases, nonimmunogenic (*16, 17*). In fact, experiments that clearly demonstrate specific antitumor immunity have been mainly restricted to virally and chemically induced laboratory tumors (*18, 19*).

Klein and Klein (*20*) have proposed that immune surveillance against virus-induced tumors involves preselection of immune response genes favoring rejection responses directed against virus-associated antigens. The nonrejectabil-

best copy available

ity of spontaneous tumors may thus be attributed to the lack of such immune response gene preselection. According to this view, antigenic modification of the tumor cell membrane might prove useful in overcoming the genetically determined immune unresponsiveness of the host. Indeed, it has been shown that viral xenogenization (*21*, *22*), chemical modification (*23*), and somatic cell hybridization (*4*) could significantly increase the immunogenicity of otherwise weakly immunogenic tumors.

In a previous study (*2*) we investigated the in vitro induction of cell-mediated immunity against radiation- and RadLV-induced leukemias. It was found that generation of cytotoxic T-cells against syngeneic RadLV-infected tumors required preimmunization (priming) of the responding lymphocyte donor with the corresponding tumor cells. The cytotoxic response was induced by and directed at virus-associated antigens expressed on the tumor cell membrane. X-ray-induced tumors did not express virus antigenicity and were therefore resistant to cytotoxicity.

We have established several cell lines, derived from X-ray-induced thymomas of C57BL/6 origin, that remained virus-negative during propagation in vitro. The characteristics of one cell line, designated PIR-2, are documented in the present study. PIR-2 expressed the serologically defined H-2^{b} alloantigens, as well as the T-cell marker Thy 1.2. It does not react with anti-RadLV, anti-gp70, and anti-p30 antisera. In vivo priming and subsequent in vitro sensitization of C57BL/6 lymphocytes with PIR-2 do not result in the generation of anti-PIR-2 cytotoxic cells. With the use of the same procedure, 136.5 and EL-4 tumor lines, known to express C-type virus antigenicity (*2*, *9*), could efficiently induce antitumor cytotoxic responses. Furthermore, cytotoxic lymphocytes generated against 136.5 or EL-4 lyse both 136.5 and EL-4 tumors but not PIR-2 targets, and neither of the lines is lysed by 136.5-primed lymphocytes cocultivated with PIR-2 cells.

Immunogenicity of tumors in vivo can be evaluated by the antitumor protective effect of preimmunization with inactivated tumor cells and by the enhancement of tumor growth in animals whose immune system has been impaired by irradiation. PIR-2 was found to be nonimmunogenic according to both of these criteria. Immunization of C57BL/6 mice with PIR-2 had no effect on either PIR-2, EL-4, or 136.5 tumor growth, whereas mice immunized with EL-4 or 136.5 were partially protected against a challenge with either EL-4 or 136.5, but not with PIR-2 cells. Exposure of mice to 400 rad whole-body irradiation enhanced the takes of EL-4 tumors, whereas there was no effect on PIR-2 tumor growth.

It was therefore of interest to determine whether the PIR-2 thymoma could be rendered immunogenic after hybridization with an allogeneic tumor cell. For this purpose, PIR-2 cells were fused with the universal fuser A9HT, and establishment of the A9/PIR somatic cell hybrid was confirmed by chromosome analysis and the coexpression of H-2^{b} and H-2^{k} alloantigens. The MuLV-related antigens present on A9HT were fully expressed on the hybrid. In contrast, the Thy 1.2 antigen of PIR-2 was not detected in A9/PIR.

We initially investigated the ability of A9/PIR to induce cytotoxic responses in vitro. When C57BL/6 lymphocytes were sensitized with irradiated A9/PIR cells, cytotoxic lymphocytes capable of lysing PIR-2, EL-4, and YBA (that share the *H-2*^{k} haplotype with A9HT) were generated. YBA cells were used as targets for detection of anti-*H-2*^{k} allocytotoxicity since A9HT cells could not be efficiently labeled by $Na_2{}^{51}CrO_4$; background isotope release exceeded 40% during the cytolysis assay (5 hr). Cocultivation of C57BL/6 lymphocytes with A9HT or a mixture of A9HT + PIR-2 did not result in generation of anti-PIR-2 cytotoxicity. It thus appears that after hybridization with A9HT, PIR-2 acquired the ability to stimulate cytotoxic lymphocytes capable of recognizing and lysing parental PIR-2 cells. The generation of cytotoxicity by the A9/PIR hybrid did not require preimmunization of the responding lymphocyte donor. Several possibilities may account for this observation: *1*) Low expression of a putative TSA on PIR-2 is increased after hybridization to a level sufficient for stimulation of cytotoxic lymphocytes; *2*) the allogeneic A9HT cell membrane acts as an adjuvant for the TSA of PIR-2; *3*) the responding lymphocytes are stimulated by a modified TSA expressed on the hybrid and can still recognize original, nonimmunogenic TSA on parental PIR-2 cells, bringing about their lysis.

Cytotoxic lymphocytes generated against syngeneic MuLV-infected tumor cells are mainly stimulated by virus-modified self H-2 antigens (*24–26*). Since both MuLV and H-2^{b} antigens are expressed on A9/PIR, it is conceivable that the anti-EL-4 cytotoxic response of C57BL/6 lymphocytes sensitized by the hybrid is directed against the MuLV-H-2^{b} complex also expressed on EL-4 (*2*).

After the in vitro investigation we proceeded to study the immunogenicity of the hybrid in vivo. For this purpose, A9/PIR-preimmunized mice were inoculated with different numbers of viable tumor cells, and the rate of tumor growth was evaluated. Preimmunization with the hybrid had a protective effect against a challenge with EL-4 and 136.5, while it significantly enhanced PIR-2 tumor growth. This observation implies that correlation between cytotoxicity in vitro and inhibition of tumor growth in vivo obviously cannot be postulated. Prehn (*27*) suggested that a weak immune reaction may stimulate tumor growth rather than inhibit it. It can thus be assumed that A9/PIR induced a weak immune response against TSA expressed on PIR-2 resulting in stimulation of PIR-2 tumor growth. In contrast, the virus-related anti-EL-4 and 136.5 response generated by the hybrid is stronger and therefore sufficient to inhibit tumor growth.

The effectiveness of immunization with A9/PIR on both EL-4 and PIR-2 takes was dependent on the dose of inoculated viable tumor cells. An optimal inhibition and enhancement of EL-4 and PIR-2, respectively, was achieved when the animals were challenged with 10^{5} cells. Preimmunization with the hybrid was less effective when larger or smaller doses of tumor cells were injected, suggesting that a very high or low tumor inoculum may more easily escape the impact of a preexisting immune response.

In conclusion, our results clearly demonstrate that a nonimmunogenic tumor modified by somatic cell hybridization can be rendered immunogenic. However, a possible application of this approach for immunotherapy is questionable in view of the stimulatory effects of hybrid preimmunization on parental tumor cell growth.

Purification and Transplantation of Hepatocytes From Livers of Carcinogen-Treated Rats[1,2,3]

Steven B. Miller,[4] Theresa P. Pretlow,[4,5] Joe A. Scott,[4]
and Thomas G. Pretlow II[6,7]

ABSTRACT—Young adult male F344 rats were given 90 ppm diethylnitrosamine in drinking water for 5 weeks. Cells were obtained in suspension from the livers of these animals by in situ perfusion of collagenase. Cells were separated in a 2.7–16% (wt/wt) continuous gradient of Ficoll in tissue culture medium in the Sorvall TZ-28 reorienting zonal rotor for 10 minutes at 4°C with a centrifugal force of 12×*g* at the sample–gradient interface (26×*g* at the gradient–cushion interface). Up to half a billion liver cells were separated without exceeding the band capacity. In all experiments the purest fractions contained more than 90% hepatocytes. After centrifugation, 72.4±6.6% of the purified hepatocytes had histochemically demonstrable γ-glutamyl transpeptidase (GGT). When purified hepatocytes were injected into the mesenteric veins of rats given a diet containing 0.02% (wt/wt) *N*-2-fluorenylacetamide for 7 days and subjected to partial hepatectomy, all rats that received these cells developed foci that exhibited histochemically demonstrable GGT. Hepatocytes with histochemically demonstrable GGT make up all or part of what previously has been referred to as "liver colony-forming units." With the TZ-28 reorienting zonal rotor, these cells can be purified in biochemically preparative quantities.—JNCI 1982; 68:851–857.

The process of carcinogenesis involves at least two stages: initiation, which is irreversible and takes place over a short period of time, and promotion, which is at least partially reversible and takes place over an extended period of time [recently reviewed in (*1–3*)]. Although it is still useful to talk about the stages of initiation and promotion, it is now widely recognized that carcinogenesis is a multistep process (*1–3*). In hepatocarcinogenesis, enzyme-altered foci occur soon after the administration of carcinogens and long before carcinomas appear (*4–7*). In a recent review, Miller and Miller (*3*) stated: "The evidence suggests that these foci of hepatic cells are precursors of hepatic tumors, but whether or not some of the cells in these foci are neoplastic has not been determined." We do not know how closely any of the phenotypes of these enzyme-altered foci is linked to malignant transformation.

The purification of subpopulations of cells with defined rates of sedimentation from the livers of animals exposed to carcinogens makes available subpopulations with a limited range of phenotypic characteristics that can be readily determined. The orthotopic grafting of these phenotypically characterized subpopulations would permit their biologic activity to be tested, i.e., their ability to generate enzyme-altered foci and/or carcinomas in suitably prepared hosts. Recently, a technique (*8, 9*) has been developed for the transplantation of precursor cells during hepatocarcinogenesis into syngeneic host rats. We now report our use of this technique to test the ability of purified, enzyme-altered hepatocytes to form enzyme-altered colonies in the livers of syngeneic hosts. The method used for cell separation will permit the purification of as many as a half a billion liver cells in a single, 10-minute centrifugation.

MATERIALS AND METHODS

Animals.—Male F344 rats were obtained from animals bred and maintained in the University of Alabama in Birmingham animal facility from a strain originally obtained from the Charles River Breeding Laboratories (Wilmington, Mass.). The animals were housed at a maximum of 4 per cage and maintained on a 12-hour light cycle with free access to tap water. They were fed a standard laboratory diet (Wayne Lab-Blox-8604-00; Professional Animal Diet, Wayne Pet Food Co., Vinemont, Ala.) ad libitum.

Diet.—At 90–110 g, donor rats were continued on the standard laboratory pellets, but 60 (*10*) or 90 ppm DENA (Eastman Kodak Co., Rochester, N.Y.) was added to their drinking water. The animals received the DENA for 5 weeks ± 3 days. Fresh DENA in water was prepared and changed twice a week. The carcinogen was removed and replaced with tap water 72 hours prior to killing.

Rats that were to receive transplanted liver cells were allowed to achieve a weight of 150–250 g. Seven days prior to receiving transplanted cells, the host animals were placed on a 0.02% (wt/wt) 2-FAA diet (Bio-Serv Inc., Little Silver, N.J.) as used by Laishes and Rolfe (*9*). The transplantation of cells and partial hepatectomy were accomplished during the same laparotomy. Seven days after partial hepatectomy and injections of cells, the 2-FAA was discontinued, and the standard laboratory pellets were reinstituted.

ABBREVIATIONS USED: DENA=diethylnitrosamine; EGTA=ethyleneglycolbis(β-aminoethyl ether)*N,N'*-tetraacetic acid; 2-FAA=*N*-2-fluorenylacetamide; GGT=γ-glutamyl transpeptidase; JMEM=Joklik's modification of Eagle's minimum essential medium.

[7] We thank Dr. George Michalopoulos, Duke University School of Medicine, Durham, N.C., for his advice regarding the preparation of liver cells in suspension and the use of collagen membranes to assess the viability of liver cells; and Mrs. Katherine Sexton, University of Alabama in Birmingham, for her excellent assistance in the preparation of this manuscript.

Suspensions of cells.—For each experiment 1–6 rats were used as donors. Suspensions of liver cells were prepared by a modification of the method of Berry and Friend (*11*). The animals were anesthetized with ether, the abdomen was opened, and the vena cava was entered inferior to the liver with an 18-gauge angiocatheter. A clamp was placed on the vena cava superior to the liver. Both the portal vein and hepatic artery were incised for drainage. With a peristaltic pump, the liver was perfused at a rate of 20 ml/minute with 50 ml of 5 m*M* EGTA (Sigma Chemical Co., St. Louis, Mo.) in JMEM (Grand Island Biological Co., Grand Island, N.Y.) followed by 250 ml of 0.05% collagenase (Worthington type I; Worthington Diagnostics Div., Millipore Corp., Freehold, N.J.) in JMEM at room temperature. Following perfusion, the liver was excised, weighed, minced to fragments of approximately 3 mm in greatest dimension, and incubated at 37°C in 20 ml of the described collagenase solution for 20 minutes. The liver fragments were then dispersed mechanically. The cells were centrifuged at 97×*g* for 7.5 minutes at 4°C, resuspended in cold 10% horse serum in JMEM, filtered through 40-μm Nitex (TETKO Inc., Elmsford, N.Y.), and counted with hemacytometer chambers. We assessed cell viability by observing the ability of cells to exclude trypan blue. In some experiments, the ability of liver cells to attach to collagen membranes was assessed.

Cell separation.—Liver cells were separated with a TZ-28 reorienting zonal rotor (Dupont Instruments, Sorvall Operations, Newtown, Conn.) in a Sorvall RC-5B refrigerated centrifuge (Dupont Instruments). Speed was monitored with a Sorvall Portac (Dupont Instruments). The cushion, gradient, and sample were loaded dynamically, while the speed of the rotor was 500 rpm. The 60-ml cushion was made of equal parts of a 32.8% (wt/vol) solution of sodium metrizoate (Hypaque; Nyegaard & Co., Oslo, Norway) and a 10% (wt/wt) solution of Ficoll (polysucrose; average mol wt, 400,000; Pharmacia Fine Chemicals, Piscataway, N.J.) in JMEM. A continuous Ficoll gradient was formed with a two-chambered gradient generator as previously described by Pretlow et al. (*12*) and later modified by Green et al. (*13*). The 1,250-ml gradient used in our experiments varied from 2.7% (wt/wt) Ficoll at the sample–gradient interface, 4.2 cm from the center of revolution, to 16% (wt/wt) Ficoll at the gradient–cushion interface, 9.3 cm from the center of revolution. The gradient was allowed to equilibrate in the rotor for 90 minutes at 4°C prior to use. When less than half a billion cells were separated, a 16-ml sample was used. When more than half a billion cells were separated, a 50-ml sample was used. The sample was dynamically loaded with a syringe in 10–30 seconds. The cells were sedimented at 500 rpm for 10 minutes at 4°C with a centrifugal force of 12×*g* at the sample–gradient interface. After centrifugation, the rotor was slowly decelerated over 10–15 minutes.

Gradient fractions.—We unloaded the gradient statically by siphoning 40-ml fractions at a rate of 40 ml/minute. Cell counts were performed on all fractions with hemacytometer chambers. Multiple sets of permanent slides were prepared from the starting sample and from each fraction with a Cytocentrifuge (Shandon Southern Instruments Inc., Sewickley, Pa.). The slides were stained in parallel with Wright-Giemsa stain and for GGT as described by Rutenberg et al. (*14*) and modified by Jacobs et al. (*15*). Differential counts of 500 cells were performed on each fraction. To confirm the linearity of the gradient, we measured refractive indices with the Abbe-3L refractometer (#33-45-58-01; Bausch & Lomb Inc., Rochester, N.Y.).

Transplantation of cells.—The four purest fractions (fractions 12–15) of hepatocytes from the separation of a half a billion liver cells were pooled in a 250-ml centrifuge tube and diluted with 100 ml of JMEM to decrease the viscosity. The cells were centrifuged at 97×*g* for 7.5 minutes at 4°C and resuspended in JMEM at a concentration of 1×10^6 cells/ml. The viabilities of the cell suspensions were estimated, and slides were prepared and stained as previously described. Cells were transplanted by the method of Laishes and Rolfe (*9*). On the 7th day of 2-FAA feeding, the host rats were anesthetized with ether, a midline abdominal incision was made, and a partial hepatectomy was performed by the method of Higgins and Anderson (*16*). A small loop of intestine was gently removed from the abdominal cavity. A mesenteric vein was isolated, and 1 ml of the cell suspension was infused through a 26-gauge needle over 20–30 seconds. The needle was withdrawn, and a small piece of Gelfoam (The Upjohn Co., Kalamazoo, Mich.) was gently held on the injection site until hemostasis was achieved. The loop of intestine was placed back into the abdominal cavity, and the abdomen was closed. On the 10th day after transplantation of cells, the host rats were killed by prolonged exposure to ether. The animals were weighed, and the livers were excised. Multiple slices of liver were taken for frozen sections. Two contiguous sections were taken from each slice to be stained for GGT activity and with hematoxylin and eosin.

RESULTS

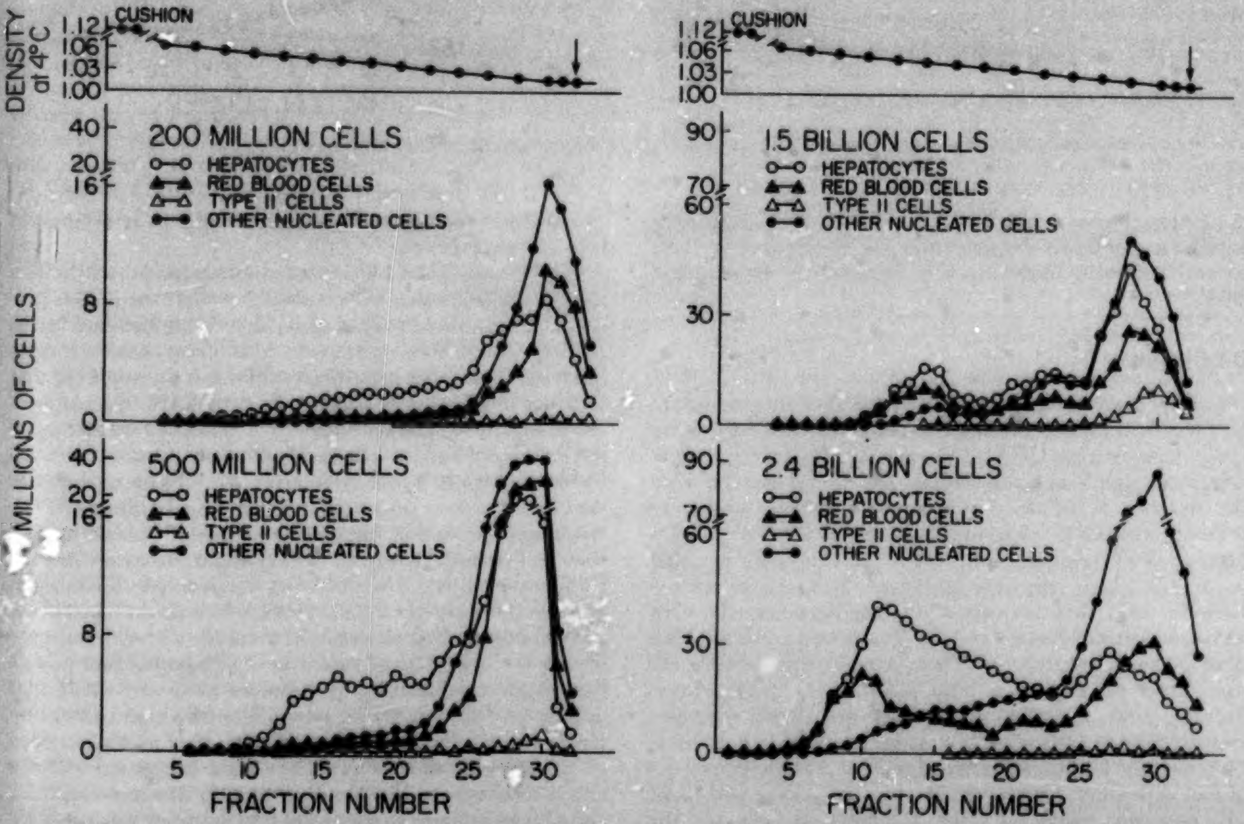
Starting sample.—Animals that received 90 ppm DENA had a greater proportion of hepatocytes with histochemically demonstrable GGT than animals that received 60 ppm DENA and were used for all separation and transplantation experiments. We obtained an average of 355.3±65.3 million cells per liver; 87.7±4.8% of the cells excluded trypan blue. The starting sample suspensions of cells contained 52.4±12.0% hepatocytes, 32.1±7.8% other nucleated cells, and 15.5±5.2% erythrocytes as determined by morphologic evaluation of Wright-Giemsa-stained preparations. Similar preparations are illustrated in an earlier report (*15*). When stained for GGT, 68.4±10.3% of the hepatocytes exhibited activity. Of the nonhepatocytes, 3.8±1.7% had histochemically demonstrable GGT. These have been termed "type II cells," are probably oval cells, and were illustrated in a color plate published previously (*15*).

Rotor separation.—Between 188 and 517 million liver cells were separated without exceeding the band capacity. In those experiments when band capacity was not exceeded, the total recovery of cells was 93.8±2.5% of the cells introduced into the rotor. In all experiments, fractions were obtained that had more than 90% hepatocytes. When more than half a billion cells were introduced into the rotor, both the purity and the total recovery of cells decreased. The recovery from gradient centrifugations of 1.0, 1.5, and 2.4 billion cells was 77.9, 73.2, and 63.8%, respectively.

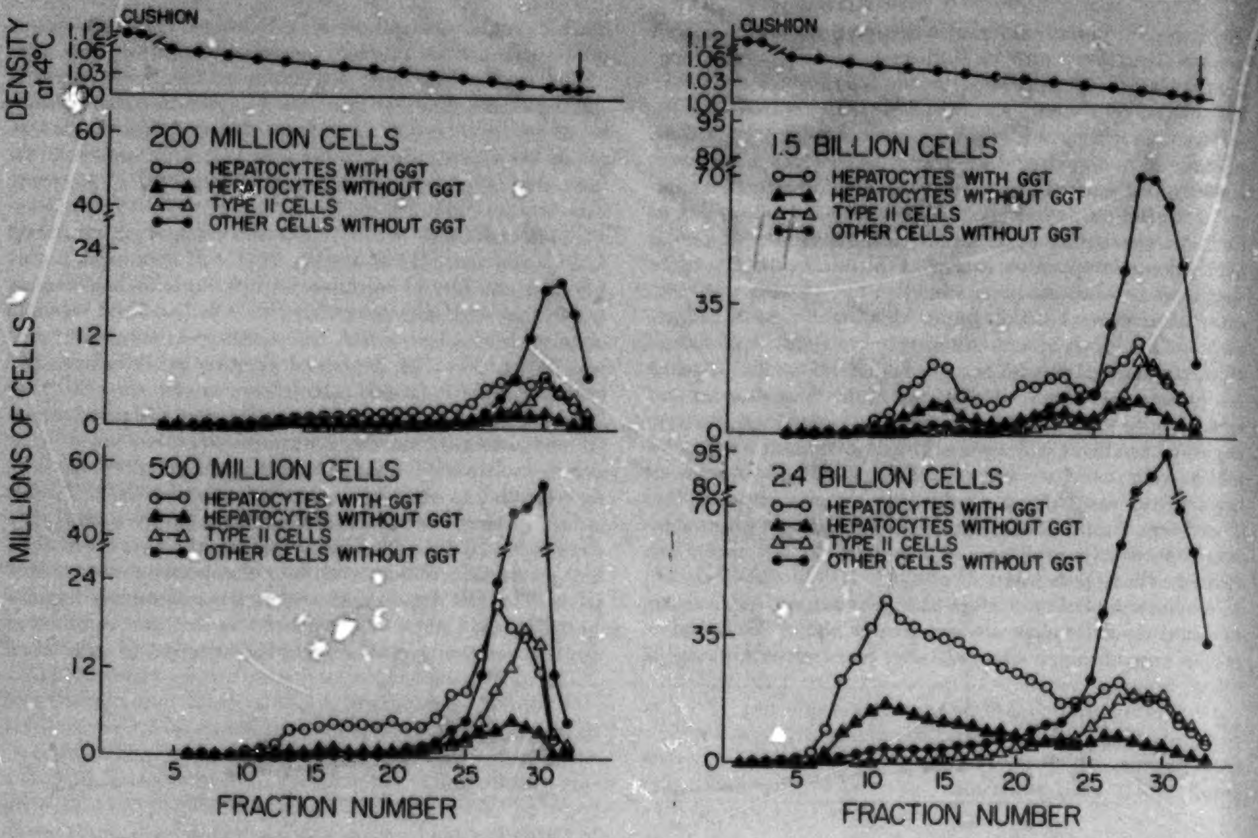
When 188–517 million liver cells were separated, the fractions containing the purest hepatocytes were located between fractions 4 and 15. In these fractions, 93.2±1.3% of the nucleated cells were hepatocytes. Up to fraction 20, over 80% of the cells were hepatocytes (text-fig. 1). When both 1.0 (not shown in text-fig. 1) and 1.5 billion cells were separated, it appeared that the gradient had been overloaded. As discussed previously (*12*), when the band capacity of a gradient is exceeded, cells sediment farther, i.e., to fractions containing more rapidly sedimenting cells. In the experiments in which we exceeded the band capacity, there was a broadening of the curves (text-fig. 1) with a shift of cells that sediment slowly under ideal conditions into fractions that ordinarily contain highly purified hepatocytes. With the overloading of the gradient and the loss of ideal conditions, there was a loss of purity in those fractions of rapidly sedimenting cells that previously contained mostly hepatocytes. The gradient was grossly overloaded when 2.4 billion cells were sedimented. The modal population of hepatocytes was shifted all the way down to fraction 11. There were 6 million nucleated cells in fraction 11 that were not hepatocytes, and they represented 10.2% of the nucleated cells in that fraction.

When estimated by dye exclusion, viability of hepatocytes in fractions 5–24 was always greater than 75%. Similar results were obtained when viability was assessed by attachment to collagen membranes at 24 hours. This observation is consistent with previous reports comparing these two methods (*17*). The large population of hepatocytes seen at the top of the gradient was mostly nonviable. This finding is consistent with the observation that dead cells sediment much less rapidly than viable cells (*12*). It is important to note that hepatocytes with and without GGT sediment similarly (text-fig. 2).

Transplantation of cells.—The combined and concentrated four purest fractions (fractions 12–15) of hepatocytes contained a sample for injection with 97.4±1.4% hepatocytes (excluding erythrocytes). After the cells had been washed, counted, and concentrated, the viability of the injected cells was 55.0±3.0%. The decreased viability resulted from the repeated centrifugations used to concentrate the cells. Frozen sections of all livers taken at the time of partial hepatectomy showed that there was almost no histochemically demonstrable GGT (fig. 1). As early as 4 days after injection, we were able to see periportal foci of cells with GGT. Twelve animals from three separate experiments survived until they were killed 10 days after transplantation. Livers from all 12 had numerous colonies with histochemically demonstrable GGT. The foci (fig. 2) appeared to be composed of hepatocytes (fig. 3). Control rats undergoing the same regimen as the hosts but without receiving the injection of cells failed



TEXT-FIGURE 1.—Distribution of the various cells in DENA-exposed liver after sedimentation in the TZ-28 zonal rotor at 4°C for 10 min with a centrifugal force of 12×*g* at the sample–gradient interface. Differential counts of 500 cells were performed on Wright-Giemsa-stained slides of each fraction. *Arrows* mark the sample–gradient interface on the density plots.



TEXT-FIGURE 2.—Distribution of the various cells based on GGT-stained slides of the same fractions illustrated in text-fig. 1.

to develop the same type of foci with GGT. Occasional cells with histochemically demonstrable GGT were seen in these control rats; this observation is discussed in more detail later.

DISCUSSION

Laishes and Rolfe (*9*) demonstrated that the transplantation of initiated liver cells gave rise to foci with histochemically demonstrable GGT and to hepatocellular carcinomas. The most significant correlation they found was between the number of viable cells injected and the number of colonies with GGT that were formed. Since they used a heterogeneous population of liver cells, they were not able to identify which cells were responsible for the liver colony-forming units they measured in their assay system. Our recipient rats developed colonies that were similar, but we used purified hepatocytes. These experiments provide the first direct proof that at least some of the liver colony-forming units described by Laishes and Rolfe (*9*) were derived from enzyme-altered hepatocytes. It does not, however, exclude additional types of cells as possible precursors of foci with GGT. Our work, like that of Laishes and Rolfe (*9*), does not prove "... that the injected cells are the progenitors of GT(+) colony cells"; exploration on that subject awaits the use of appropriate markers such as "... definitive cytogenetic markers to follow the progeny of colony precursor cells ..." (*9*).

While many have minimized the importance of the fact that 0.02% 2-FAA in the employed semisynthetic diet produces a variable but often easily detectable increase in the activity of GGT in rat livers, this point deserves some discussion. In citing a publication from his group (*18*) that includes the feeding of 0.02% 2-FAA (2-AAF) in a semisynthetic diet to F344 rats, Farber (*1*) states: "The dietary 2-AAF does not induce foci under these conditions, when fed for up to 4 weeks[16] [our reference (*18*)]." In fact, when one examines the data presented in chart 6 by Tsuda et al. (*18*), there is an increase in the number of hepatic foci with GGT that Tsuda et al. (*18*) term "a very slight increase when the feeding period was 4 weeks." On the average, this increase appears to be greater than threefold. Laishes and Rolfe (*19*) have discussed their observation that cells with GGT appear during the treatment of rats with 0.02% 2-FAA and partial hepatectomy as used by us; however, cells with GGT that appear on this diet are clearly different in size and nature from cells in colonies obtained 10 days after transplantation of hepatocytes with GGT. The "resolving power" of the image analyzer used by Tsuda et al. (*18*) was such that "the actual minimum size of a lesion that could be measured by this method was 0.2 mm in diameter." This threshold in size would exclude most of the cells with GGT in the livers of animals maintained on 0.02% 2-FAA without transplanted hepatocytes with GGT while including the majority of colonies arising from hepatocytes with GGT infused via the mesenteric veins as performed in our experiments.

In our experiments, we separated 12 times more liver cells than have been separated with other methods of velocity sedimentation (*20*) while maintaining equal purity of hepatocytes. The large numbers of purified hepatocytes can now be further purified into different subpopulations by additional, sequential techniques such as free-flow electrophoresis (*21*) and adherence chromatography. We would also like to separate the hepatocytes with GGT from the hepatocytes without this enzyme. Enzyme-altered hepatocytes have lost the ability to store iron (*6, 22*). Williams (*6*) has suggested that the administration of an iron overload to rats treated with carcinogens might alter the physical properties of the hepatocytes that accumulate iron and facilitate the use of physical methods for the purification of the enzyme-altered hepatocytes that do not accumulate iron.

We also observed a large population of nonviable hepatocytes at the top of the gradient. We suspect that, as a result of the carcinogen feeding, these hepatocytes are much more fragile than nonaltered hepatocytes. This view is supported by the fact that when normal liver cells are subjected to similar velocity sedimentations, this population is not seen (*20, 23*). The carcinogen regimen received by the animals to be used as donors was similar to that used previously (*10, 22*) except that we used 90 ppm DENA instead of 40 or 60 ppm DENA to obtain a larger proportion of hepatocytes with GGT. It provided large numbers of enzyme-altered hepatocytes while there was only minimal oval cell proliferation (*10, 22*). Three rats were observed over a period of several months after treatment with 90 ppm DENA. All 3 were killed when moribund and had multiple hepatomas. Two of these 3 animals had pulmonary metastases.

Reorienting gradient zonal centrifugation provides a method by which large quantities of cells and subcellular particles can be purified (*24*). In addition to the rotor's large capacity, the rotor offers the advantage that direct comparison has shown that a larger proportion of the cells from the starting sample are recovered from this rotor than can be recovered after isokinetic sedimentation (*13, 25*). The superior recovery of cells from the rotor results from its unique design that eliminates the wall effect seen with parallel-walled tubes (*12*).

In recent years this rotor has been used for the isolation of yeast in various phases of the cell cycle (*26*), calf thymus nuclei (*27*), rabbit renin granules (*28*), human blood and marrow cells (*29*), mouse ascitic tumor cells (*13, 30*), human tonsillar cells (*25*), and rat hepatocytes (*23*). Both Wells et al. (*29*) and Daugherty et al. (*25*) were able to culture their cells after they were purified in this rotor. When implanted into mice, separated malignant cells retained the capacity to form tumors (*13*). The large capacity and high recovery reported by these investigators suggested that this rotor can provide an effective means for purification of sufficient numbers of enzyme-altered hepatocytes to permit a detailed analysis of their biochemical and biologic characteristics. If one considers the large numbers of cells needed for many liver cell assays (*31, 32*), including our own, this rotor will facilitate studies that were not previously possible with purified enzyme-altered hepatocytes.

Malignant Fibrous Histiocytomas Induced by 4-(Hydroxyamino)quinoline 1-Oxide in Rats[1,2]

Yoichi Konishi,[3] Hiroshi Maruyama,[3] Yoshio Mii,[4] Yoshizumi Miyauchi,[4] Yoshihiko Yokose,[3] *and* **Kenji Masuhara[4]**

ABSTRACT—Subcutaneous and bone malignant fibrous histiocytomas (MFH) were induced in high incidence in rats by 4-(hydroxyamino)-quinoline 1-oxide (4-HAQO). Subcutaneous MFH were induced locally by repeated weekly injections of 1 mg 4-HAQO/rat for 4 weeks. Between 16 and 48 weeks after the final treatment, 13/15 (87%) male noninbred Wistar rats developed tumors. The histologic subtypes of these tumors were as follows: 11 fibrous, 1 myxoid, and 1 giant cell. Bone MFH were induced between 18 and 25 weeks by implantation of 4-HAQO (8 mg/rat) into the bone marrow of the tibia in 12/14 (86%) male noninbred Fischer 344 rats. The histologic subtypes of these tumors were as follows: 6 fibrous, 4 myxoid, and 2 giant cell. Morphologically, these MFH appeared similar to human MFH.—JNCI 1982; 68:859–865.

Since the early description of MFH by O'Brien and Stout (*1*), this type of malignant neoplasm has remained controversial because of its uncertain histogenesis. In 1978, Weiss and Enzinger (*2*) described MFH to be primitive, pleomorphic sarcomas showing partial fibroblastic and histiocytic differentiation, as indicated by collagen production and occasional phagocytosis, and reported that MFH could be distinguished from pleomorphic variants of liposarcomas, fibrosarcomas, or rhabdomyosarcomas. Subsequently, histologic features of MFH permitting differential diagnosis from other tumors have been reported (*3, 4*). It is now evident that MFH develop in soft tissues in various sites of the body, including bone (*5*), that they are the most common soft tissue sarcoma of late adult life, and that the prognosis is poor (*6–8*). It is obvious that an animal model of human MFH is needed for the study of the pathogenesis of this malignant neoplasm. It has been reported that subcutaneous MFH was induced in rats by potential carcinogens and by some plant extracts and their tannin-containing fractions (*9*), and experimental approach to fibrous histiocytoma in syngeneic mice inoculated with transformed bone marrow macrophages has been reported (*10*). However, these reports do not constitute an animal model of MFH since the former experimental approach involved multiple injections of carcinogens for a long time, and the latter one was a mixture of in vitro and in vivo systems. This paper communicates briefly the induction of subcutaneous and bone MFH by 4-HAQO in rats.

MATERIALS AND METHODS

Fifty-nine, 6-week-old, approximately 180-g male noninbred Wistar rats (Kiwa Animal Farm, Wakayama, Japan) or Fischer 344 rats (Nippon Charles River Animal Farm, Tokyo, Japan) were used. 4-HAQO (Nakarai Chemical, Ltd., Kyoto, Japan) was dissolved in 40% DMSO at 2 mg/ml and was injected into the subcutaneous dorsal tissue at 1 mg/rat once a week for 4 weeks. Injections were made in the same subcutaneous area that had been marked at the time of the first injection. 4-HAQO, a yellow powder, was inserted into the bone marrow of the left tibia as follows: Rats were anesthesized with ether. The front of the tibia about 1 cm distal from the knee joint was exposed surgically, the periosteum and the cortical bone were incised, and 8 mg 4-HAQO/rat was inserted aseptically with a small curet. A sham operation was made in the same way in some rats, except that 4-HAQO was not inserted.

The experimental groups were as follows: Group 1 Wistar rats received 4 sc injections of 0.5 ml 40% DMSO/rat; group 2 Wistar rats received 4 sc injections of 4-HAQO; group 3 Fischer 344 rats were subjected to the sham operation; and group 4 Fischer 344 rats received the surgically implanted 4-HAQO. All rats were housed in wire cages in an air-conditioned room at 24°C and were given Oriental MF diet (Oriental Yeast Co., Ltd., Tokyo, Japan) and water ad libitum. The initial and effective numbers of rats and the times of sacrifice are shown in table 1.

Complete autopsies with careful macroscopic examinations were performed. Subcutaneous and bone tumors, subcutaneous tissue at the site of injections, visible pathologic regions, and major internal organs such as lung, liver, pancreas, kidney, and spleen were fixed in 10% buffered Formalin or Bouin's solution. Bones were decalcified as described by Plank and Rychlo (*11*). All tissues were embedded in paraffin, sectioned, and stained with H & E. Special stains such as periodic acid–Schiff, alcian blue, azan Mallory, and Van Gieson's stains were used when necessary.

For electron microscopic studies, small pieces of tumor tissues were fixed in 2.5% glutaraldehyde in 0.1 *M* phosphate buffer for 2 hours, washed three times with 0.1 *M* phosphate buffer containing 0.25 *M* sucrose, and again fixed in 1% osmium tetroxide in 0.1 *M* phosphate buffer for 1 hour. The samples were then dehydrated in a graded series of alcohols and embedded in Epon-812. Ultrathin sections made with an LKB-8800 ultramicrotome were first examined with toluidine blue staining by light microscopy and were then stained with uranyl acetate and lead citrate and examined

RESULTS

Tumor Incidence

The initial and effective number of rats, the incidence of tumors, the time of sacrifice, and tumor size are shown in table 1. Five rats from group 2 died of pneumonia, and no tumors were found in those rats. Subcutaneous tumors were induced in 13/15 (87%) group 2 rats, and bone tumors were found in 12/14 (86%) group 4 rats. No tumors of other sites were found in rats from groups 2 and 4, and no tumors developed in rats from groups 1 and 3. The tumors in group 2 rats appeared between weeks 16 and 48, and tumors in group 4 rats appeared between weeks 18 and 25. The tumors grew rapidly after they became visible or palpable.

Pathology

Tumors in group 2 rats were located in the subcutaneous tissue at the injection site, whereas tumors in group 4 rats were in the tibial bone (fig. 1). Some large bone tumors showed invasion to the cortical bone and periosseous soft tissue. Tumors in rats from groups 2 and 4 appeared similar. They were hard, and their cut surfaces were lobulated and grayish white or yellowish white. Some tumors had a diffuse or partly jelly-like appearance. Inguinal lymph node and/or lung metastases were observed in 2 rats from group 4. Tumors in rats from groups 2 and 4 had essentially the same histologic pleomorphic appearance. These tumors were classified according to the description of Weiss and Enzinger (*2*), as shown in table 2.

Fibrous MFH consisting of spindle cells grew in focal areas with a storiform (matting-like) arrangement (figs. 2, 3). Osteoid reaction in the tumor was seen in a group 4 rat, but tumor osteoid was not seen. Variants of this type showed pleomorphism with bizarre tumor giant cells, Touton or epulis giant cells, and/or xanthomatous cells. Mitotic figures were frequent. The predominant feature of the giant-cell type was the presence of bizarre tumor giant cells and epulis giant cells. Storiform arrangement was not predominant (figs. 4–6). Mitotic figures were frequent. The myxoid type exhibited diffuse myxomatous change, staining with alcian blue, and contained bizarre tumor giant cells (figs. 7, 8). This type of MFH rarely had a storiform arrangement. Various extents of lymphocyte infiltration were seen in these types of tumor. The fibrous type was found in 11/13 (84%) group 2 rats and in 6/12 (50%) group 4 rats. Metastases were fibrous-type MFH. Electron microscopic examination showed that the tumors consisted of three major cell types: fibroblast-like cells, histiocyte-like cells, and undifferentiated cells (fig. 9). Collagen fibers were seen in the interstitial spaces, but bundle formation was not seen. Fibroblast-like cells, which were frequently seen in fiber-proliferating areas, were spindle shaped, elongated, or polygonal. Their nuclei were smooth surfaced, and their cytoplasm contained a dilated rough endoplasmic reticulum and microfilaments

[b] ILD=inguinal lymph node.

with focal densities. Histiocyte-like cells were rounded, their nuclei were indented with a clear nucleolus, and their cytoplasm contained many lysosomes, small vacuoles, and pinocytotic vesicles. The surface of these cells had many microvilli. Undifferentiated cells were relatively small and round. Their round nuclei contained dispersed chromatin, their cytoplasmic organelles were poorly developed, and their nuclear:cytoplasmic ratio was high. Intermediate-type cells, which could not be distinguished from fibroblast-like or histiocyte-like cells, multinucleated giant cells, and xanthomatous cells, were also observed.

DISCUSSION

In the present work, we induced MFH in subcutaneous tissue and bone marrow by treating rats with 4-HAQO. This compound is a reduction product (*12*) of the carcinogen 4-nitroquinoline 1-oxide (*13*), which was shown to induce subcutaneous tumors on local application (*14–16*), mesodermal cancers on ip injection (*17*), and pancreatic tumors on iv injection (*18, 19*). Previously, the subcutaneous sarcomas induced by 4-HAQO were described as fibrosarcomas (*15*). However, the experiment was performed in the early 1960's, when the entity of MFH had not yet been described. Since then there has been much recent progress in histologic diagnosis of MFH, and as a result, it is controversial whether these sarcomas are MFH.

Subtypes of MFH in human cases have been classified on the basis of criteria suggested by Kempson and Kyriakos (*20*) and Weiss and Enzinger (*2*). Enjoji et al. (*7*) divided MFH into four types—common, myxoid, xanthogranulomatous, and giant cell— and further divided the common type into predominantly pleomorphic and predominantly storiform subtypes. Kearney et al. (*21*) divided MFH into four types—fibrous, giant cell, myxoid, and inflamamtory.

In the present work, rat subcutaneous and bone tumors were diagnosed as MFH and were classified into three major subtypes: fibrous, giant cell, and myxoid. Indeed, it was difficult to distinguish the different subtypes because mixtures with components of the various cell types occur in varying proportions; nevertheless, a type of MFH is predominantly fibrous and occurs frequently. Spontaneous MFH in rats has been reported (*22*), but rat MFH is different from its human counterpart; however, in the present experiment we could observe subtypes of MFH which are classifiable in humans. Furthermore, the cell populations observed electron microscopically in rat MFH may corresponded to those observed in human MFH (*23, 24*).

In the present work, subcutaneous and bone MFH were induced by 4-HAQO, a suggestion that chemical carcinogens may be important in the development of human MFH. Further experiments are required on the induction of MFH with other carcinogens in various animal species. Spontaneous subcutaneous tumors occur in laboratory animals in long-term feeding experiments, and spontaneous MFH have been reported only in rats (*22, 25, 26*) and in dogs and cats (*27*). In this connection, histologic re-evaluation of spontaneous tumors in laboratory animals may be required. Nevertheless, induction of subcutaneous and bone MFH by 4-HAQO in rats provides a useful experimental model for studying the histogenesis and characteristic growth behavior of MFH.

Prostate Adenocarcinoma in Rats: Induction by 3,2′-Dimethyl-4-aminobiphenyl[1,2,3,4]

Shoichi Katayama,[5,6] Emerich Fiala,[5] Bandaru S. Reddy,[5] Abraham Rivenson,[5] Jerald Silverman,[5] Gary M. Williams,[5] *and* **John H. Weisburger[5,7,8]**

ABSTRACT—Five experiments designed for various purposes [mainly for the study of colon carcinogenesis in inbred F344 male rats given sc injections of 3,2′-dimethyl-4-aminobiphenyl (DMAB)] were reviewed as to the production and presence of neoplastic lesions of the prostate gland. The overall incidence of prostate proliferative lesions among 293 animals exposed to DMAB was 32% (95 animals). Early in situ carcinomas were present in 66 animals, larger intra-acinar carcinomas in situ in 28, and invasive carcinoma in 1. None of the control animals in these studies exhibited prostate neoplasms. The conclusion, therefore, is that DMAB can induce adenocarcinomas in the rat prostate gland. JNCI 1982; 68:867–873.

Chemical carcinogens with an organotropism for almost every organ of the rodent have been identified, and with the use of these chemicals, organ site models for cancer induction have been developed. A notable exception is the prostate gland. Although many attempts have been made to induce cancer in this organ, there are no reliable means for chemically inducing prostate adenocarcinomas through systemic action (*1–18*). A naturally occurring prostate carcinoma in rats more than 30 months old of the ACI–Segaloff strain was described in detail in (*19*).

Chemicals that have induced prostate carcinoma in rats and mice include benzo[*a*]pyrene (*1*) and 3-methylcholanthrene (*2–4*). However, the prostate gland had to be exposed directly to these chemicals by insertion of a carcinogen-containing pellet (*2–4*) or by direct injection of a carcinogen (*1–3*). The tumors induced were, in most cases, squamous cell carcinomas which are quite rare in humans. Recently, Pour (*20*) reported squamous carcinomas induced through the systemic action of *N*-nitrosobis(2-oxopropyl)amine in MRC rats. Prostate tumors have also been produced by X-irradiation (*6, 7*).

Among the derivatives of 4-aminobiphenyl, DMAB has been known to be a multipotential carcinogen for the large and small intestine, mammary gland, ear duct, salivary gland, and urinary bladder of the rat, either by sc injection or oral administration (*21–28*). In a study on the effects of disulfiram on the carcinogenicity of DMAB in rats and hamsters, we noted a small number of in situ carcinomas in the prostate glands of rats, but not in hamsters, exposed to DMAB (*29*).

One reason for performing studies with DMAB at our institute is the close chemical similarity of this synthetic carcinogen to certain mutagens isolated from cooked meat or fish (*30–33*). There is an association, in turn, between the incidence of cancer of the colon, breast, and prostate gland in meat-eating populations. Vegetarian populations, such as Seven-Day Adventists, have a much lower incidence of these diseases (*34, 35*). It is of great interest, therefore, that the synthetic chemical DMAB should be able to induce in rats the three types of cancer which appear to exhibit certain parallel characteristics in geographic pathology.

Consequently, all ongoing studies with DMAB at this institute were carefully evaluated for the occurrence of prostate lesions, including one experiment designed and conducted to validate and extend the findings of Fingerhut and Veenema (*5*) in inducing prostate carcinoma. In this report, we describe the effects of DMAB on the prostate glands of rats in five separate experiments.

MATERIALS AND METHODS

This report records procedures and findings for five experiments performed at the Naylor Dana Institute (*26–29*). Although the experiments had different purposes, the animals used were from the same strain of inbred rats, CDF (F-344)/CrlBR, and were from the same source (Charles River Breeding Laboratories, Inc., Portage, Mich., or Kingston, N.Y.), except for experiment III in which germfree F344 rats (from Charles River Breeding Laboratories stock bred in our institute) were used. In each experiment, the carcin-

ogen was DMAB (Ash-Stevens, Inc., Detroit, Mich.; or the Extramural and Intramural Carcinogenesis Programs, NCI, through the carcinogen repository, Illinois Institute of Technology, Chicago, Ill.). The DMAB was dissolved in corn oil and injected sc once a week. The basal diet was NIH-07 (Zeigler Bros., Gardeners, Pa.) in experiment IV; Purina Laboratory Chow (Ralston Purina Co., St. Louis, Mo.) in experiment I; and a powdered semipurified diet, AIN-76, with different fat or fiber contents (Bioserve, Inc., Frenchtown, N.J.), in experiments II, III, and V (table 1).

Experiment I, March 1976–June 1977.—Seventy-five F344 male rats were divided into 3 groups: 30 were treated with DMAB only, 30 had DMAB and disulfiram in the diet, and the appropriate controls (*29*). DMAB, 20 mg/kg body weight, was injected sc once a week for 37 weeks. From the starting group of 60 DMAB-exposed rats, 46 were available for study. Total experiment period was 68 weeks.

Experiment II, April 1978–February 1979.—Sixty-three F344 male rats were initially used and were divided into 5 groups (*27*). Injections of 50 mg DMAB/kg body weight once a week for 20 weeks were given to 48 rats that were on either a low-fat (5% beef tallow in a semipurified diet) or a high-fat diet (20% beef tallow in a semi-purified diet). Among the DMAB-treated animals, 44 were available for evaluation. Total experiment period was 42 weeks.

Experiment III, April 1978–April 1979.—The animals in this experiment were germfree F344 rats, a line maintained in our institute since 1976 (*26, 27*). Injections of 50 mg DMAB/kg body weight once a week for 20 weeks were given to 77 rats that were on either the low-fat or high-fat diet as described above; 6 rats served as vehicle controls. Of the DMAB-treated rats, 68 were examined in this study (table 1). Total experiment period was 50 weeks.

Experiment IV, February 1979–April 1980.—Of the 189 F344 male rats in this experiment (*28*) 135, on either 15% wheat bran in the control diet or 15% citrus pulp in the control diet, were given injections of 50 mg DMAB/kg body weight once a week for 20 weeks. Fifty-four controls and sentinels for health testing were on either the basal control diet or one of the fiber diets. Total experiment period was 60 weeks.

Experiment V, August 1978–April 1980.—This experiment was designed to extend the findings in (*5*). When groups of gonadectomized male rats were given iv injections of 10 mg DMBA, as in (*5*), most died. Therefore, larger groups of gonadectomized rats were given three iv injections of 5 mg DMBA every 2 weeks and then were held as described in table 1. Other groups were given iv injections of 2 mg MNU, a mammary carcinogen (cf. *36*), and thus reasoned to be a putative prostate carcinogen. For the same reason, DMAB, a carcinogen active on the colon and breast of the rat, was administered as described below.

Fifty-one F344 male rats were divided into 4 groups. At 90 days of age, 48 rats were orchiectomized. One month later, injections of 20 mg DMAB/kg body weight once a week for 40 weeks were given to 42 of the castrated animals that were on either a low-fat (5% lard in a semipurified diet) or high-fat diet (33% lard in a semipurified diet). The remaining castrates served as vehicle controls or untreated

[a] Data from 5 experiments, with diverse-specific aims, that were performed at our institute, March 1976 through April 1980.

[b] Low fat diet: 5% beef tallow; high fat diet: 20% beef tallow.

[c] Germfree F344 strain maintained at our institute were used. (For details, *see* text.)

[d] All animals were castrated at 90 days of age, according to procedure of Fingerhut and Veenema (*5*). Low fat diet: 5% lard; high fat diet: 33% lard.

[e] Vehicle controls and untreated animals of all experiments. The longest experiment with normal rats lasted 68 wk.

[f] Control group of experiment performed in 1980–81, extending over 82 wk.

controls. Total experiment period was 86 weeks—the longest of the five experiments.

Tissue processing, all experiments.—At the end of each experiment, all survivors were killed with CO_2 and then necropsied. During the experiments, animals that appeared moribund were killed. All available prostate tissues were submitted to histologic examination in 10% buffered Formalin. The samples were trimmed in a sagittal plane to include the urinary bladder and dorsal and ventral lobes of the prostate gland in one histologic piece. After paraffin embedding, four to five sections at various levels were cut and stained with H & E.

RESULTS

DMAB is known to induce cancer of the colon and breast. In our institute, we have used DMAB to study the pathogenesis of colon and breast cancer and the influence of a number of modifying elements, such as the enzyme inhibitor disulfiram, or certain nutritional components, such as fat or fiber (*26-29*). In connection with the first of these tests involving disulfiram, the inadvertent observation was made that male rats that were given 20 mg DMAB/kg body weight (expt I) for 37 weeks and held for a total of 68 weeks exhibited in situ carcinomas of variable size in the prostate gland. For this reason, we reviewed specifically the prostate tissue sections and data obtained in the remainder of the experiments with DMAB (which were originally designed to provide information on the pathogenesis of colon cancer) and performed a detailed microscopic study.

In all five experiments, no obvious manifestation of disease in the prostate gland was apparent. Of the five experiments, four involved normal rats, whereas the fifth experiment used male rats that were gonadectomized at age 90 days. Microscopically, neoplastic lesions in prostate tissues were seen in nongonadectomized F344 rats treated in experiments I–IV with DMAB. Although the weekly dose was different in the four experiments (20 or 50 mg/kg), the total dose administered in all four experiments was of the same order of magnitude (241–296 mg DMAB). The amount of carcinogen did not seem to influence greatly the overall yield of prostate tumors. However, the length of the observation period apparently did affect the total tumor yield which was higher in the more extended periods, especially in experiment IV. In summary: In all four experiments, 33% of the animals had various degrees of carcinoma development in situ; in experiment II, 1 invasive adenocarcinoma developed; in experiment IV, the yield of carcinoma lesions in situ was as high as 60%; the modifiers (specifically disulfiram), fats or fiber levels, or germfree status had no obvious effect.

All lesions were located in the ventral lobe of the prostate gland. The microscopic alterations in affected prostate tissues included an overgrowth of the epithelial lining of the acini which "piled up" and formed secondary micro-acini that assumed the well-known cribriform pattern. This pattern occurred even in the smallest incipient lesions (figs. 1, 2). Cytologically, the overgrown cells were obviously dysplastic, with vesiculated nuclei containing one or two relatively distinctive nucleoli (fig. 2).

No notable morphologic differences in the prostate neoplasms were observed among the experiments, except in the size of the lesion. In more advanced cases, proliferating epithelial cells occupied almost the entire space of one or several acini (figs. 3, 4) but without obvious invasion into the adjacent tissue. In some cases the neoplasms were multifocal but, even so, they were confined to the ventral lobes. Secretory products were observed in the neoplastic acini. In one rat from experiment II, an overt tumor of the prostate gland was present. Grossly, it was a firm yellow mass, 1.5×0.9×0.6 cm, which presented on the left dorsal lobe of the prostate gland. Histologic examination revealed this tumor to be an invasive adenocarcinoma (figs. 5, 6).

In gonadectomized rats from experiment V, no gross or microscopically visible lesions were observed in prostate tissues, even though the experiment was extended to 86 weeks. This finding was not only true for the carcinogen DMAB (table 1) but also for NMU and DMBA (data not given). With DMBA, we encountered high mortality within weeks after injection of the carcinogen at the level used by Fingerhut and Veenema (10 mg) and also at 5 mg. Thus it seems quite clear that three kinds of carcinogens, which are thought to have an effect on the prostate gland, failed to be active in gonadectomized rats. Dr. R. Kroes (personal communication) also could not reproduce the original results of Fingerhut and Veenema (*5*).

DISCUSSION

This report provides an extension of an inadvertent observation made during an experiment for the study of the pathogensis of cancer at important sites in humans (large bowel and breast) as induced in rats by the chemical carcinogen DMAB. A gross enlargement of the prostate gland led to a detailed study of microscopically visible lesions in all prostate tissues in experiments performed at this institute on F344 male rats given DMAB. We found that this chemical administered once a week by sc injection could, through systemic action, induce lesions in the prostate gland, specifically in the ventral part of the gland, that ranged from minute carcinomas in situ, with an incidence up to 38%, to large carcinomas in situ, with an incidence up to 20%. There also was 1 invasive adenocarcinoma. Metastases were not seen. More tumors were seen in the tissues of the groups used in the longer experiments. A recent paper (*37*) dealt with the spontaneous prostate adenocarcinoma incidence in control and certain treated F344 rats, approximately 2 years of age or older, in the NCI bioassay program.[9] In this population of old rats, less than 1% had adenocarcinoma, and an average of about 3.6% had adenoma. However, in certain participating laboratories, an incidence as high as 15% was noted. Nonetheless, the DMAB model described herein provides a means to obtain higher yields of prostate adenocarcinoma in a shorter time under highly controlled conditions.

---

[9] In a more recent experiment involving normal, nongonadectomized F344 rats and extending over 82 wk, an untreated control group of 30 rats had 3 animals with carcinoma in situ and 1 animal with an early (small) carcinoma in situ (table 1, footnote *f*).

We are reporting these findings at this time because DMAB is the first available systemically acting chemical that reliably induces prostate adenocarcinoma. Modification of the experiment protocols may lead to improved yields, especially of the more advanced lesions. Such studies are currently planned and in part have been initiated at this institute, particularly since DMAB has a structure similar to certain naturally occuring dietary compounds suspected of being associated etiologically with the development of cancer in the colon, breast, and prostate gland (*32–44*).

It will be important to study the underlying endocrine situation, inasmuch as prostate cancer is likely under endocrine control, as is breast cancer and, therefore, possibly is subject to dietary modulation (*36, 45–48*). The model described should be useful to study systematically the modifying factors, such as diet and the endocrine elements, under highly controlled conditions. Thus, as in the case of breast cancer (*36*), such model studies can provide background information on the pathogenesis and etiology of prostate carcinoma in humans (*36, 49*).

Comparison of In Vitro and In Vivo Effects of Thymidine on L1210 Leukemia in Mice[1]

Daniel S. Zaharko[2,3] *and* **Lori M. Ramonas**[2,4,5]

ABSTRACT—Previous investigators have shown that L1210 leukemia in vitro growth can be inhibited by thymidine (dThd) by exposure for 24 hours to dThd concentrations as low as 0.1 m*M*. These experiments were conducted in an attempt to determine why dThd, although effective as a cytostatic agent against L1210 in vitro, is ineffective against L1210 in (BALB/c×DBA/2)F_1 (CD2F_1) mice. Systematic variations of dThd concentration and exposure times were examined in both a growth-inhibition assay and a soft agar cloning assay in vitro. The growth of cells exposed to 0.1–1.0 m*M* dThd for 15 hours was inhibited dramatically during exposure, but growth recovered to control rate rapidly when dThd was washed off the cells. With 96 hours of exposure to 1.0 m*M* dThd, growth rate did not return to control rate up to 120 hours after washing. Cloning efficiency was reduced to less than 1% of control by prior 96-hour exposure of L1210 cells to more than 0.5 m*M* dThd. Concentrations of deoxycytidine (dCyd) of 1.0 μ*M* partially reversed cytotoxicity caused by dThd greater than 0.1 m*M*, and 10 μ*M* dCyd completely reversed this cytotoxicity. In vivo plasma dThd concentrations during ip injections of 3,600 mg dThd/kg body weight every 8 hours for 4 days (approximately lethal dose for 10% of animals treated) ranged from 10 to 0.1 m*M*, but these concentrations were ineffective in prolonging survival time of L1210-bearing mice. Plasma concentrations of dCyd prior to dThd exposure were less than 1.0 μ*M*. Following injection of dThd (3,600 mg/kg body wt), plasma dCyd was 2.8±0.5 μ*M* (normal mice) and 6.1±0.5 μ*M* (L1210-bearing mice). Thus the rise of dCyd in plasma following dThd administration in vivo prevented the cytotoxicity of dThd seen in vitro from being manifested in vivo in CD2F_1 mice.—JNCI 1982; 68:875–880.

Early reports in the literature indicate that dThd inhibits DNA synthesis (*1*) and acts as a cell-synchronizing agent (*2*). The biochemical mechanisms for these actions have been intensively studied over the intervening years and have been well summarized in a recent publication (*3*). Text-figure 1 illustrates that dThd exerts its inhibitory actions on cell functions by being converted to TTP which controls a variety of enzyme activities. The generally accepted mechanism for inhibition by dThd of cell growth is a block of the ribonucleotide reductase at the level of deoxyribopyrimidylate production (*4*). This inhibitory action can be reversed by providing dCyd (*5*). Recently, on the basis of in vitro studies and human xenograph studies in athymic mice, it was suggested that dThd might be a selective antitumor agent if high plasma concentrations (millimolar or greater) are sustained in vivo (*6, 7*). Subsequent reports, however, indicate that dThd used alone is not very useful as an antitumor agent in vivo in a variety of tumor systems (*8–11*). For the L1210 mouse leukemia in particular, it has been demonstrated that complete growth inhibition in vitro can be achieved by millimolar concentrations of dThd (*12*). However, in vivo, at doses that should have resulted in millimolar concentrations in the plasma of mice bearing ascites L1210 leukemia, no increase in life-span of the mice was observed (*9*).

In this article we confirm this anomaly and explore further the pharmacokinetic and biochemical reasons for the discrepancy between the in vitro and in vivo effects of dThd on the L1210 leukemia.

MATERIALS AND METHODS

Animals and tumors.—(BALB/c × DBA/2)F_1 (hereafter called CD2F_1) mice, 20–25 g, were used in all studies. L1210 mouse leukemia was maintained by ip passage and transplanted by iv injection into the tail veins of mice for in vivo experimental studies. Trypan blue exclusion was used to determine the number of viable cells injected. For in vitro studies these same L1210 mouse leukemia cells were grown in suspension culture at 37°C in RPMI-1630 medium supplemented with 20% heat-inactivated horse serum, L-glutamine (1, m*M*), 2-mercaptoethanol (50 μ*M*), penicillin, and streptomycin. dCyd in this supplemented media, as measured by HPLC, was less than 1 μ*M*. The number of cells used in the colony survival or in the growth assay was determined with a Coulter counter, and the viability (trypan blue, periodic checks) was greater than 90%.

Cultures used to measure the growth inhibition by dThd were maintained in an exponential growth phase at densities between 0.3 and 1.8×10^6 cells/ml. Control doubling time in this medium under these conditions is 24 hours.

The method of Chu and Fisher (*13*) for colony survival in soft agar was used to determine the viability of cells after dThd treatment in vitro. The percent colony formation of control cells was 50±4 (SD). The evaluation of antitumor activity in vivo followed the techniques of Schabel et al. (*14*). Animals dying of drug toxicity were not used in scoring the median survival day.

dThd and dCyd.—These substances were obtained from Sigma Chemical Co., St. Louis, Mo. To administer the large quantities of dThd required, we injected all in vivo doses ip in a volume of 0.1 ml/g of mouse. This solution was made

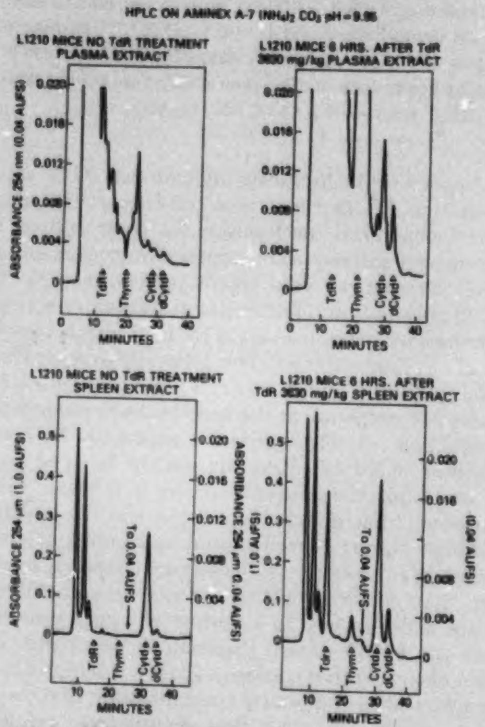
Enzymes known to be involved are: 1, ribonucleoside diphosphate reductase; 2, nucleoside diphosphokinase; 3, nucleoside dephosphorylase; 4, deoxycytidylate kinase; 5, deoxycytidylate deaminase; 6, dThd synthetase; 7, dThd kinase; 8, dCyd kinase; 9, DNA polymerase; 10 Cyd deaminase. --□--, inhibition; ----●, stimulation.

isotonic by adding the appropriate amounts of NaCl to the aqueous dThd solution. dThd was dissolved in DMEM for the in vivo infusion studies.

Chromatography.—A liquid chromatographic technique used for the measurement of nucleosides (*15*) was adapted to HPLC to resolve and quantitate dThd and dCyd from other UV-absorbing plasma and tissue components. The stainless steel column was 25 cm long × 4 mm in internal diameter and was packed with Aminex A-8 cation-exchange resin, particle size 7±1.0 μm (Bio-Rad Laboratories, Richmond, Calif.). The eluent was $(NH_4)_2CO_3$ adjusted with NH_4OH to pH 9.95 (to resolve Cyd from dCyd) or to pH 9.75 (to measure low dThd plasma concentrations). Ambient temperatures of 25°C and a flow rate of 0.2 ml/minute resulted in a pressure that fluctuated around 1,000 psi, depending on the age of the prefilter (Rheodyne, 2 μm) and precolumn (5 cm × 2 mm, A-8 Aminex), which were changed when the pressure exceeded 3,000 psi. The flow was maintained constant, independent of pressure by an Altex 110A solvent-metering pump. Peak heights were measured at 254 or 270 nm in an 8-μl flow cell with a Schoeffel SF770 spectrophotometer and quantitated with a Shimadzu C-E 1B data processor. Peak heights were proportional to the quantities of dThd and dCyd in the solution that was injected. Standard curves were linear in the utilized range. With the volumes of injections used, dThd below 1 μ*M* was undetectable, and dCyd below 0.5 μ*M* was undetectable. The plasma dThd peak was confirmed by its comigration with standard dThd on the A-8 Aminex column. Also, the postulated plasma dThd peak was collected and rerun on a Rheodyne RP-8, 25 cm × 4-mm stainless steel column eluted with 0.005 *M* NH_4 acetate (pH=4.9), 95:5 with acetonitrile (eluent flow, 1.0 ml/min). This peak from the A-8 column coeluted with a standard dThd on the RP-8 column. The dCyd peaks from plasma and spleen extracts were also confirmed by their comigration in the above two chromatographic systems with a standard dCyd. In addition, with the use of a stop-flow technique on the A-8 column, a standard dCyd peak's UV spectrum was scanned between 200 and 300 nm with a Schoeffel SF 770 coupled with an MM 700 memory module and matched that of the scan of peaks with dCyd retention times in plasma and spleen extracts. These findings, coupled with the observation that Cyd and dCyd are cleanly resolved in the above two systems, give us some confidence that we are indeed measuring changes in dCyd following the administration of high doses of dThd to mice.

Sample preparation.—Blood was collected by decapitation of the mice anesthetized a few minutes earlier with 80 mg pentobarbital/kg body weight. Spleens were removed just prior to decapitation and quickly frozen by clamping between two aluminum blocks kept in Dry Ice between each clamping. The blood was centrifuged (1,500×*g* for 15 min), and the plasma was collected and frozen. Three volumes of methanol were added to each thawed volume of plasma. The precipitate was spun at 12,000×*g* in an Eppendorf centrifuge and discarded; the supernatant was dried at 50°C under slight vacuum to create an airflow. The dried supernatant was made up with the eluting buffer to half the volume of the original plasma volume used. A precipitate formed, which was centrifuged (12,000×*g*), and an aliquot of the supernatant was used to inject into the HPLC chromatographic column. The frozen spleen was processed in the same manner except 3.5 ml methanol/g spleen was used and the initial step was to blend with a Tekmar homogenizer with microprobe. The methanol-dried fraction was made up in 0.7 ml eluting buffer/g spleen weight. Calculations for concentrations per milliliter of plasma or per gram wet weight of spleen were made. Recoveries were 95±5% for dThd and 80±5% for dCyd when these substances were added to plasma and then extracted.



Text-figure 2.—HPLC chromatographs of plasma and spleen extracts from mice. Aminex A-8 column eluted with $(NH_4)_2CO_3$ (pH=9.95) at 25°C; flow rate, 0.2 ml/min. AUFS=absorption units full scale: TdR=dThd; Thym=thymine; Cytd=Cyd; dCytd=dCyd.

RESULTS

Text-figure 2 illustrates typical HPLC chromatograms of plasma and spleen extracts from mice. All subsequent quantitative calculations are made from such typical chromatograms.

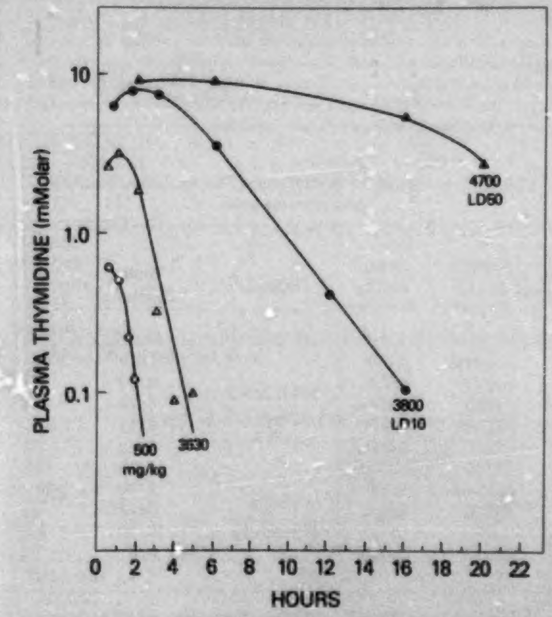
In Vivo Plasma Kinetics

Text-figure 3 illustrates results of plasma concentrations of dThd in mice following single doses that ranged in toxicity from nonlethal to lethal. Note the change in half-life as doses progress from nonlethal to lethal. On the basis of these data, we chose a dose around 3,600 mg/kg body weight for subsequent therapeutic tests. The assumption was that this dose, if repeated every 8 hours, would sustain a plasma concentration of dThd between 0.1 and 10 m*M* during the major portion of the dosing interval.

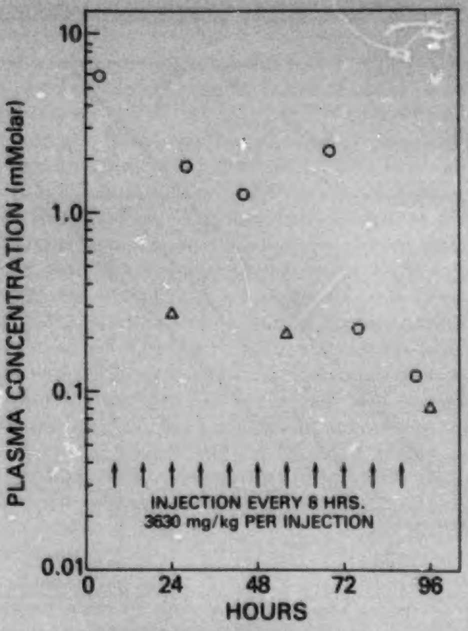
Text-figure 4 data confirm this assumption when the dosing period was 4 days. A critical dThd concentration of above 0.1 m*M* was selected because of previous reports (*12, 16*) that maximal growth suppression of L1210 in vitro was achieved above concentrations of 0.1 m*M* when growth inhibition was measured during exposure to dThd.

In Vitro Cytostatic and Cytotoxic Response

We confirmed this above finding of growth inhibition with our L1210 leukemia cells. Growth of these cells during 96 hours of exposure to dThd was one-tenth or less that of controls when dThd concentrations were 0.1 m*M* or greater. In addition, we collected data (text-fig. 5) illustrating that after the dThd is washed off, L1210 cells may recover rapidly from their growth inhibiton. The time of exposure to dThd as well as the concentration is important in the determination of the degree of inhibition and the time to recovery.



Text-figure 3.—Plasma dThd of CD2F$_1$ mice following a single ip dose of dThd in a volume of 0.1 ml/g body wt. *Each point* represents an HPLC analysis of a pooled plasma extract from 3 mice. LD10=10% lethality; LD50=50% lethality.

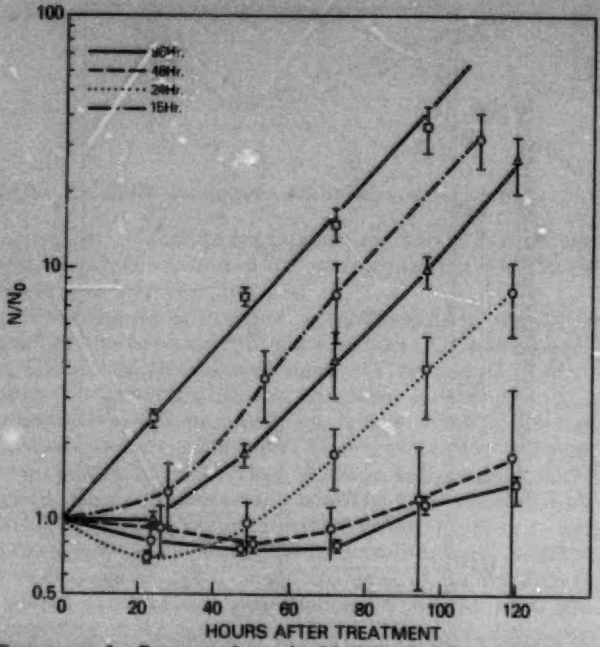


Text-figure 4.—Plasma dThd of CD2F$_1$ mice following multiple ip doses of dThd in a volume of 0.1 ml/g body wt. *Each point* represents an HPLC analysis of a pooled extract from 3 mice. ○=4 hr after injection. △=8 hr after injection. The first injection was at zero hour.

To determine to what extent this inhibitory effect of dThd was cytotoxic, we then conducted a colony survival assay of L1210 following a 4-day exposure to various concentrations of dThd. Text-figure 6 illustrates two findings. First, dThd indeed is cytotoxic to L1210 cells and results in a 3-log cell kill at a concentration of 1.0 m*M* maintained for 4 days prior to cloning. Concentrations below 0.1 m*M* are, however, only slightly cytotoxic, and concentrations between 0.1 and 1.0 m*M* are intermediate in toxicity. Second, if present during the dThd exposure at the proper concentration, dCyd can reverse the cytotoxicity. The proper concentration for 1 m*M* dThd appears to be between 5 and 10 µ*M* dCyd.

In Vivo Therapeutic Response

Our first in vivo therapeutic experiment was designed to determine whether single doses of dThd could affect the growth of L1210 in vivo. Table 1 presents data that indicate neither dThd administration twice a day nor three times a day for 4 days slows the growth of L1210 in vivo as determined by the survival time of mice. Notice also the wide range of toxicities seen on the same schedule, which indicates perhaps a variable pharmacokinetic behavior of dThd in individual mice. Because of the rapidly changing plasma concentrations resulting from such single doses and the earlier in vitro findings indicating that sustained high dThd concentrations were necessary to maintain inhibition of growth or result in cytotoxicity in vitro, we conducted an in



TEXT-FIGURE 5.—Recovery of growth of L1210 cells following treatment with dThd. Cells were suspended at a density of 1×10^6 cells/ml and grown for various times (15, 24, 48, and 96 hr) in normal or dThd-containing media. They were then all washed three times in fresh normal medium and reincubated in fresh normal medium at a density of 2.5×10^5 cells/ml. dThd treatment: ○=1 m*M*; △=0.1 m*M*; □=no dThd. N/NO=No. of cells in drug-treated tubes/No. of cells in control tubes.

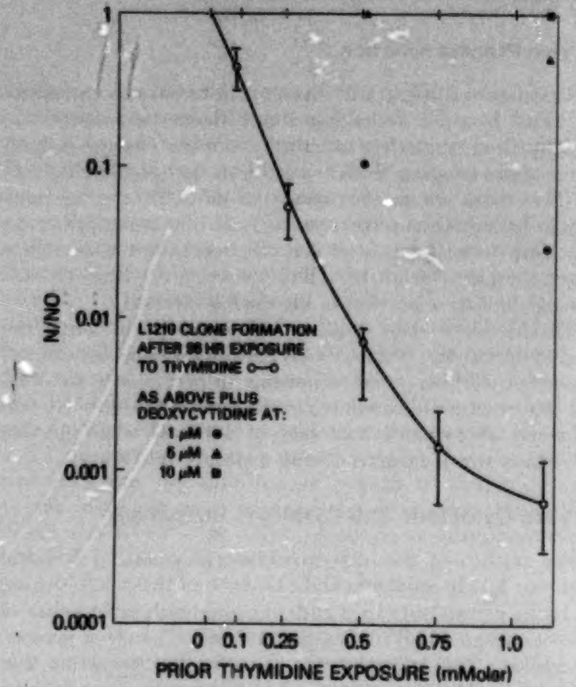
vivo experiment in which we infused dThd ip for 4 days. We monitored the plasma dThd by daily sampling tail vein blood.

Table 2 presents these data. Control animals that died of tumor died mainly between days 7 and 8. Animals that died of dThd toxicity died much earlier (day 1, 2, or 3) and had plasma dThd concentrations around 10 m*M*. dThd-infused animals that died of tumor had plasma dThd concentrations around 1.0–2.0 m*M* for each of the 4 days of infusion. This difference between plasma steady-state dThd concentrations in mice manifesting drug toxicity and in mice dying of tumor verifies the variable pharmacokinetic behavior of dThd in individual mice. Similar results indicating the lack of antitumor action at maximally tolerable dThd infusions have been obtained in a different mouse strain [(C57BL × DBA)F_1 (BDF_1)] with L1210 in independent studies in another laboratory (*16*). These in vivo data indicated that the resistance of L1210 in vivo to dThd under these dose schedules was more likely due to a biochemical reason rather than to a pharmacokinetic one.

Text-figure 6 presents data indicating that dCyd between 5 and 10 μM is necessary to reverse the cytotoxicity of dThd in an in vitro colony survival assay. We therefore looked in vivo at dCyd concentrations in normal animals and L1210-bearing animals receiving high doses of dThd.

Plasma and Spleen dCyd

Our first experiment was to determine the recovery of added dCyd (1×10^{-5} *M*) from normal, dThd-untreated mouse blood at 0 and 37°C. The recovery of dCyd was consistently 75% even with incubation times up to 2 hours at 37°C. This phenomenon indicates that the CDF_1 mouse strain lacks significant deaminase activity in the blood in



TEXT-FIGURE 6.—Colony survival assay of L1210 cells after 96 hr of exposure to various concentrations of dThd and dCyd. Cells were exposed at a density of 1×10^6 cells/ml. The culture medium was changed daily, and the cells were washed three times prior to seeding in soft agar at three densities (10^2, 10^3, and 10^4 cells/ml). Visible colonies were counted after 10 days and again after 14 days of incubation at 37°C. Agreement between these two counts was excellent. N/NO=No. of colonies in drug-treated tubes/No. of colonies in control tubes.

TABLE 1.—*Antitumor activity of dThd on L1210-bearing and normal mice*

contrast to that of another strain (BDF_1) (*16*).

Table 3 indicates that after dThd treatment the plasma dCyd concentration rises in both normal and L1210-bearing mice. The plasmas of L1210 mice after dThd treatment have a higher concentration of dCyd than those of normal mice, and this difference is statistically significant ($P<0.01$). Recall that a dCyd concentration of 5 μM or above is sufficient to reverse the cytotoxic response of dThd measured in the colony survival assay in vitro.

There is also a statistically significant difference ($P<0.001$) between the plasma dThd concentration of normal dThd-treated mice and L1210 dThd-treated mice. It appears from these data and the plasma dThd data presented in table 2 that some L1210 mice are unable to clear dThd from their blood as rapidly as most normal mice.

A regression analysis was run between all the plasma dThd and simultaneous dCyd concentrations from multiple injection experiments in which mice were killed for blood from 2 to 24 hours after a dThd injection ip of 3,600 mg/kg body weight. We analyzed 37 samples, 3 pooled mice/sample. The regression equation for dCyd on dThd is $Y=0.0023X+1.33$ μM with a standard error of Y on X of ±1.5 and a correlation coefficient of 0.70. Thus higher dThd concentrations extracellularly in vivo are roughly related to higher dCyd concentrations extracellularly. This correlation could theoretically result because of a rise in TTP intracellularly, which would influence the balance among dCyd nucleotide production, utilization, and degradation (*see* text-fig. 1).

Table 3 also presents data from the spleens of mice. Note the higher dCyd in L1210 mice. L1210 grows extensively in the spleens of these mice.

DISCUSSION

These studies set out to further our understanding of the action of dThd alone by comparison of its in vitro and in vivo effects on L1210. Because of the rapid clearance of dThd from the body, we thought that it should be established that the lack of an antitumor effect was not attributable to a pharmacokinetic problem of inability to sustain plasma concentrations. We have shown that both concentration and exposure time are important. These data suggest that even with frequent single high doses of dThd, concentrations in the millimolar range are difficult to sustain in plasma. Even in those cases in which the maximal tolerable concentration of dThd was administered by injection or infusion to L1210-bearing mice, no demonstrable cytotoxic or cytostatic effect on L1210 growth was evident. It is evident, though, that much variability exists from individual mouse to mouse in the manner in which dThd is cleared from the blood. Note the variable toxicity with similar doses in table 1 and the relationship of plasma concentration with toxicity in table 2 and text-figure 3. The intolerable dThd plasma concentration in $CD2F_1$ mice is somewhere between 2 and 10 m*M* if sustained. We have discussed this toxicity in more detail in an earlier publication (*17*).

Our observation of consistent recovery of dCyd from blood incubated at 37°C for prolonged periods indicates the lack of a deaminase for dCyd in the blood of these mice.

The observation of a rise in dCyd in mouse plasma after dThd administration, particularly the higher levels in L1210-bearing mice compared to the levels in normal mice, was at first somewhat puzzling. Cyd deaminase, for which dCyd is a good substrate, is present in high activities in mouse liver, kidney, and leukemic mouse spleen (*18–21*). These high enzyme activities might be expected to maintain the low dCyd concentrations that we find in normal mice and result in even lower levels in L1210-bearing mice, which we observed. There are various conflicting reports of the inhibition by TTP of Cyd deaminase, depending on the source of enzyme (*18–20*). The enzyme from leukemic mouse spleen has been reported not to be inhibited by concentrations of TTP up to 3 m*M*. Therefore, we expected a fall in dCyd after excess dThd because of the well-documented inhibition of the only known source for de novo production of deoxynucleotides, ribonucleotide reductase, by TTP and the lack of inhibition of the deaminase primarily responsible for catabolic removal of dCyd. However, deoxycytidylate deaminase is potently inhibited by TTP at concentrations as low as 0.2 m*M* (*21*). We therefore speculate that the

Table 3.—*dThd and dCyd concentrations in plasmas and spleens from normal and L1210-bearing animals*[a]

interplay between formation of the dCyd nucleotides and their removal by deaminases and dephosphorylases intracellularly must be affected by the extracellular supply of both dThd and dCyd. There must be a response to this interplay of enzymes (*see* text-fig. 1) in various organs in vivo that results in a rise in plasma dCyd, and thus we speculate a maintenance of the dCyd nucleotides intracellularly in L1210. These data support the concept that in vivo L1210 cells use circulating plasma dCyd and/or dThd to form their dThd and dCyd nucleotides.

However, since there is no external source of dCyd in vitro, unless supplied, the excess production of TTP from excess dCyd does result in a depletion of dCyd nucleotides and hence inhibition of DNA synthesis, which the cells can apparently tolerate for only a finite time before death occurs.

The potential of dThd as a single therapeutic agent is not encouraging (*22*). However, because of its unique characteristics in modulation of biochemical pathways involved in DNA synthesis and its potential in combination chemotherapy, dThd needs continued study. Initial studies of dThd in combination with methotrexate (*9*), 5-fluorouracil (*23*), and β-cytosine arabinoside (*24*) suggest that further exploration of this mode of use may be fruitful. Further understanding of the subtle mechanism of action of dThd in vivo may be helpful in this regard.

These studies also indicate that caution should be exercised when extrapolating from in vitro drug effects to anticipated in vivo drug effects.

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

Gordon Research Conference

"Statistics in Chemistry and Chemical Engineering" is the subject of this conference to be held at the New Hampton School, New Hampton, New Hampshire, on August 2-6, 1982. Participants will discuss new developments in statistical methodology and new applications of statistics in chemistry-related areas.

Requests for applications to the conference, or additional information, should be addressed to Dr. Alexander M. Cruickshank, Director, Gordon Research Conferences, Pastore Chemical Laboratory, University of Rhode Island, Kingston, Rhode Island 02881 (telephone: 401-783-4011).

Seventh European Symposium on Hormones and Cell Regulation

Sainte-Odile (near Strasbourg), France, will be the site of this symposium to be held on October 4-7, 1982. The main topics of this conference are: synthesis of peptides and precursors; steroid action and gene expression; germ cell development; regulatory peptides in reproduction; insulin action; arachidonic acid cascade; cyclic nucleotide metabolism; and bioenergetics and calcium distribution.

The general attendance is limited to 120 persons on a first-come first-registered basis. Participants may present posters related to the topics of the conference. For detailed information on the program and registration, please write to Dr. R. Denton, Department of Biochemistry, University of Bristol Medical School, Bristol BS8 1TD, Great Britain (U.K.).

Southeastern Cancer Research Association Meeting

The Southeastern Section of the American Association for Cancer Research (Southeastern Cancer Research Association) will meet at the Quality Inn, Gatlinburg, Tennessee, on October 14-15, 1982. The meeting format will include scientific presentations from Association members and a special symposium entitled "Growth Factors, Viruses, and Protein Phosphorylation."

The meeting is open to all medical researchers and scientists. For additional information, please contact Dr. Wayne E. Criss, Cancer Center, Howard University, Washington, D.C. 20059.

Seventh International Symposium of the World Association of Veterinary Microbiologists, Immunologists, and Specialists in Infectious Diseases

Barcelona, Spain, will be the site of this meeting entitled "Infectious Diseases of the Gastro-Intestinal Tract in Bovine and Porcine Species" to be held on October 18-21, 1982.

For additional information, please write to Dr. Juan Plana Duran, Gran Via de les Corts Catalanes, 794 bajos (Chaflán Lepanto), Barcelona 13, Spain.

Chemotherapy Foundation Symposium V

The Division of Medical Oncology of the Department of Medicine, the Department of Neoplastic Diseases, and the Page and William Black Post-Graduate School of Medicine of the Mount Sinai School of Medicine will present this symposium entitled "Innovative Cancer Chemotherapy—Tomorrow" to be held at the Barbizon Plaza Hotel in New York City, on November 10-12, 1982. Dr. Ezra M. Greenspan is chairman of the meeting which will also cover recent developments in chemoimmunotherapy and biological response modifiers.

Symposium registrants are eligible for AMA Category I credits. For information on registration, please write to the Director, the Page and William Black Post-Graduate School of Medicine, Mount Sinai School of Medicine, Annenberg 5-206, 1 Gustave Levy Place, New York, New York 10029 (telephone: 212-650-6772).

Harvard Medical School Continuing Education Program

The following courses are being offered by the Department of Radiology, Brigham and Women's Hospital, and the Department of Continuing Education, Harvard Medical School:

Computed Tomography—Fifth Annual Postgraduate Course; AMA Category I credit: 28 hours; Steven E. Seltzer, M.D., Program Director; course date September 19-23, 1982.

Chest Disease—Eighth Annual Postgraduate Course; AMA Category I credit: 30 hours; Peter G. Herman, M.D., Program Director; course date October 18-22, 1982.

Angiography, Interventional Radiology, and the New Imaging Modalities—Twelfth Annual Postgraduate Course; AMA Category I credit: 28 hours; Michael A. Bettmann, M.D., Program Director; course date October 25-28, 1982.

For additional information please contact the Department of Continuing Education, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115 (telephone: 617-732-1525).

NIH Consensus Development Panel Statement Available

A National Institutes of Health Consensus Development Panel has issued a report on the safety and efficacy of CT scanning of the brain. This consensus statement on "Computed Tomographic Scanning of the Brain" is now available for the medical community and the public from the Office for Medical Applications of Research, National Institutes of Health. Free, single copies may be obtained from Mr. Michael Bernstein, Office for Medical Applications of Research, Building 1, Room 216, National Institutes of Health, Bethesda, Maryland 20205.

Availability of Serum Panels

A variety of serum components (e.g., peptide hormones, viral antigens, isoenzymes, glycoproteins, antibodies, immune complexes, tumor-associated antigens, carbohydrates, phospholipids, nucleosides, etc.) have been reported to be uniquely present, or present in elevated or decreased quantities, in the sera of cancer patients, as compared to other patients or to normal individuals. The National Cancer Institute is interested in evaluating assays that have potential for the immunodiagnosis of cancer. Coded serum panels are available to evaluate assays which have given preliminary indications of discrimination between cancer patients and controls. Promising results on this coded panel may provide the basis for further support in development of the immunoassay.

Preliminary data documenting a useful test and request for a coded serum panel to evaluate it should be sent to: Immunodiagnosis Serum Panels, Building 31, Room 3A10, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205.

Scientists Center for Animal Welfare Invites New Applications

The Scientists Center for Animal Welfare invites science writers to apply for awards of $500 each for articles on any topic relating to the use of live animals in biomedical experimentation or scientific education. Awards will be made in each of two categories: articles already published and articles being prepared for publication. Applications must contain the following information:

a) Name, address, phone number, affiliation
b) Copy of the published article or an outline of the proposed article
c) Date (or estimated date) of publication, and name of magazine, journal, or newspaper
d) Estimated length of proposed article
e) Samples of previously published work (submit at least two)

Awards will be based not only on the published article, or outline of the proposed article, but also on the quality of samples of previously published work. (Samples do not have to be on the subject of animal experimentation.) The purpose of the Scientists Center journalism stipends is to encourage the publication of thoughtful, thoroughly researched articles on issues surrounding the use of animals in biomedical research in the public press or in scientific journals.

The deadline for receipt of applications is September 30, 1982. The award date is November 1, 1982. Please send completed applications to: Ms. Marcia R. Feinleib, Scientists Center for Animal Welfare, Suite 221, 11325 Seven Locks Road, Potomac, Maryland 20854 (telephone: 301-983-0544).

Disposal of Laboratory Wastes Project

The International Agency for Research on Cancer, with the financial support of the Office of Safety of the National Cancer Institute of the United States, initiated a project in 1979 to evaluate methods for the disposal of laboratory wastes contaminated with chemical carcinogens. The aim of the project is to devise chemical degradation techniques for the disposal of wastes when incineration facilities are not available, and to publish these techniques in a series of manuals. The wastes include aqueous solutions and organic solvents, solid wastes, animal litter, carcasses, and contents of petri dishes. Consideration is also given to effective methods for decontaminating equipment and laboratory space, i.e., in case of accidental spills. The methods devised should be simple, practical, and inexpensive.

The approach of this program is described in *IARC Internal Technical Report No. 79/002* and *IARC Scientific Publications No. 37 and 43*, the first volumes issued in this series. The project comprises: bibliographical searches for existing methods and information about chemical reactions of the compounds that could be utilized for devising methods; investigation of new methods; and validation of any proposed methods through collaborative testing. The "decontaminated" waste arising from a given technique will also be tested for mutagenicity to ensure that the procedure does result in a detoxified product. The documents are finalized by a committee drawn from the collaborating group.

Scientists interested in this project are invited to participate. Collaboration can consist of submitting proposals, elaborations of methods, and validation of methods in inter-laboratory collaborative tests. For further information write to Dr. M. Castegnaro, International Agency for Research on Cancer, 150 Cours Albert Thomas, 69372 Lyon Cédex 2, France.

This month's cover shows electrophoretic separation on agarose gels of DNA fragments containing mouse mammary tumor virus sequences. Mammary tumor DNA from high-expressor and low-expressor mice were analyzed with the use of restriction endonuclease mapping procedures. *Arrows* identify fragments containing endogenous provirus sequences and give their sizes in kilo bases (Kb). Additional bands arise from proviruses acquired during exogenous infection (see paper by Altrock et al. on pages 1037–1041).

Journal of the National
Cancer Institute

June 1982
Volume 68
Number 6

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $7.00. Subscription price for two volumes per year in the United States, $70.00; foreign, $87.50. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20816.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20816.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols: *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40:2083–2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221–245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs.* Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Medicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3–10/Ann Intern Med 1979;90:95–99/Br Med J 1979;1:532–535/ or Lancet 1979;1:428–430).

Letters to the Editor

Cartesian Reductionism and Cancer

SIR: The guest editorial by Straus[1] uses much of the same evidence cited in my own editorial[2] a year earlier but draws the opposite conclusion, namely, that somatic mutation (or some variant thereof) is the origin of most cancer. The fact that the same evidence can be used to support such divergent views illustrates the futility of a point-by-point rebuttal, tempting as that might be. There was, however, one result that I emphasized in my analysis which is notable by its omission in Straus' editorial. The application of 3-methylcholanthrene to single prostatic fibroblasts results in malignant transformation in some of the descendents of up to 100% of the cells.[3] A similar result was recently reported when a combination of X-rays and a promoting agent was used to initiate transformation.[4] These findings illustrate the extreme susceptibility of inheritable properties of animal cells subjected to perturbing effects, most particularly when the cells are already perturbed by being in culture. They supplement many other observations that show the prevalence of heritable but not primarily genetic changes in cultured cells, including those that occur in early passages of cells explanted from embryos which lead eventually to cell lines,[5] or senescence[6] and the non-Mendelian mosaic pattern of resistance to 5-bromo-2′-deoxyuridine in populations of cells maintained in the presence of the drug.[7] While these regimens may ultimately alter the genome, this is likely to result from a complex evolution of the relationship between the genome and other affected parts of the cell, which brings me to my major point. The relationship between genes and the rest of the cell is reciprocal, not unidirectional, and represents a continuing dialogue. It is no longer productive of anything but polemics to vest exclusive rights for the heritable behavior of the cell in any single component. The cell is the minimal reproductive and functional unit of life, and the imposition of new external conditions, including carcinogens, probably results in a response of the cell as a whole. This can lead to a new state of equilibrium among all the coordinated parts of the cell, which may or may not be heritable. That the genome of the cell will respond as an integral part of the adjustment of the whole unit seems inevitable. This appears to be inherent in some of the diverse conditions known to cause genetic transpositions: the stationary growth state in bacteria, growth of *Drosophila* cells in culture, temperature changes in *Antirrhinum*.[8] None of these seem likely to act directly on DNA.

I believe the reason we keep returning to altered DNA as our model for carcinogenesis is that it is the only *established*, molecularly defined mechanism for determining heredity. This confining behavior is reminiscent of the old story of the fellow looking under a lamppost for a coin lost elsewhere because there was light where he searched. We act confidently as if the malignant transformation were the prototype of a precise mutational event, despite our knowledge that it is chiefly an unpredictably imprecise loss of the organized behavior of the cell, characterized by pleomorphism and an instability leading progressively downhill to autonomy[9]—a sort of biological entropy. There is an appropriate level at which to consider this disorganization, and it has to do with the influences that impose order on the enormous inhomogeneity of the cell. About these we know almost nothing apart from the dictum that all organization arises from preexisting organization.[10] The approach to this level transcends but also incorporates the usual mechanistic assumptions that underlie the purely physicochemical approach of present-day biology. This was recognized long ago by Niels Bohr in his concern that the methods commonly used to study life destroy or distort its defining attribute and thus lead to a type of biological indeterminacy.[11] This view has been elaborated in particular by Elsasser, also a theoretical physicist, who emphasizes the need to face the *irreducible* complexity of living things.[12] Therefore, the proper study of organisms may involve a "renunciation of [mechanistic] knowledge" similar to that which was, paradoxically, necessary to broaden and deepen our understanding of the physical universe.[11] Until we learn to think and then to work in this broadened context, we will continue to promulgate new hypotheses of carcinogenesis—in the same old reductionist way—whenever the last one begins to fade and another bandwagon comes on the scene. To restrict the pattern of our thought to the mold of conventional Cartesian reductionism is to exclude the possibility of the breakthrough to organismic thinking required to penetrate the intellectual morass of carcinogenesis.

Spontaneous Liver Tumors in Laboratory Rats

SIR: I refer to the report by Ogawa et al. in the August 1981 issue of JNCI.[1] The authors note that spontaneous liver tumors are rare in laboratory rats. I call their attention to a report on a high incidence of liver tumors that occurred spontaneously in aged germfree male and female Wistar rats.[2] Laboratory rats are not usually maintained for over 30 months, which may explain the low incidence of liver tumors reported by investigators. In more recent examinations, γ-glutamyl transpeptidase-positive foci have been observed in the livers of younger Wistar, Sprague-Dawley, and ACI rats. A possible explanation for the rare occurrence of spontaneously occurring liver tumors in laboratory rats may be that the tumors are slow-growing or that the "carcinogenic" agent(s) are of such low levels that over 30 months is required for them to develop into clearly defined liver tumors. Their etiology (etiologies) may be related to contaminants in the diets that were consumed by the rats. This possibility raises the important problem of interpreting the development in experimental rats of spontaneously developing tumors, which would be accelerated and enhanced if, in the course of bioassay procedures, the rats were administered promotional agents and not initiating agents.

Breast Cancer and Serum Cholesterol [1,2,3]

Robert A. Hiatt, [4] **Gary D. Friedman,** [4] **Richard D. Bawol,** [4] *and* **Hans K. Ury** [4,5]

ABSTRACT—Recent studies have suggested a role for dietary fat in the etiology of breast cancer. The relation of serum cholesterol and other serum lipid measures to breast cancer incidence was investigated in a cohort of 95,179 women who had multiphasic health checkups from 1964 through 1972. Through 1977, 1,035 new breast cancer cases occurred in over 752,000 person-years of follow-up. Age-adjusted incidence rates were 1.45, 1.37, 1.31, and 1.40/1,000 person-years from the lowest to the highest quartile of serum cholesterol level, respectively. Similarly, no statistically significant relation was detected between β-lipoprotein or total lipids and breast cancer. The sample size was sufficiently large to have detected a relative risk of 1.4 or larger with a probability of 99.9% at the 0.05 level of significance. The expected relation of breast cancer to established risk factors was confirmed by univariate analysis, and serum cholesterol and breast cancer were not associated after simultaneous consideration of nine other risk factors by multivariate analysis. These data suggest that the postulated causal relation between dietary fat and breast cancer does not act via an effect on circulating lipid levels.—JNCI 1982; 68:885–889.

A role for dietary fat in the etiology of breast cancer has been suggested by several lines of evidence. Internationally, breast cancer incidence is directly correlated with levels of affluence and industrialization (*1*); moreover, in populations, the highest socioeconomic class has had twice the risk of that of the lowest class (*2*). The search for etiologic factors associated with economic development and higher social position has led to extensive studies of the role of reproductive behavior and attendant hormonal influences (*3*). Recently, more attention is being paid to the etiologic role of dietary constituents (*4*). Dietary fat and breast cancer mortality have been directly correlated in human population studies (*5*) and in case-control studies in which women with breast cancer reported a higher intake of nutrients, especially of total and saturated fats, than did controls (*6*). The dietary fat hypothesis receives support also from animal studies in which rats fed a high-fat diet had a substantially higher incidence of mammary tumors than control rats fed a low-fat diet (*7*). Although it has not been shown consistently that serum cholesterol and dietary fat intake are related in cross-sectional studies, a recent prospective study detected a positive association (*8*). Moreover, serum cholesterol is also strongly correlated with dietary fat in comparisons of different populations (*9*). Thus it has been hypothesized that serum cholesterol levels might predict risk of breast cancer. To examine this hypothesis, we measured the incidence of breast cancer in a cohort of over 95,000 women who were characterized by their levels of serum cholesterol and other blood lipid measures.

SUBJECTS AND METHODS

Cohort at risk.—The population at risk of cancer consisted of women members of the KFHP. These women were 15 years of age and over and had undergone at least one MHC in the period 1964 through 1972. Variables of interest, which were collected by questionnaire and laboratory testing at the time of the MHC, were used to characterize women at the beginning of their follow-up period. These included basic demographic information, reproductive histories, use of exogenous estrogen, smoking and alcohol consumption history, previous breast symptoms and operations, diagnostic X-ray films of the chest, mammography, weight, height, and serum cholesterol, total lipid, and β-lipoprotein levels. Serum cholesterol was measured by an Auto-Analyzer (Technicon Co., White Plains, N.Y.) until the end of 1968 and by an Autochemist (AGA Corp., Stockholm, Sweden) from 1969 through 1972. Total lipids and β-lipoprotein were measured only by the Autochemist from 1969 through 1972. The frequency distributions of cholesterol levels and the age-specific mean levels of cholesterol were similar for both methods. The overall mean for women was 229.9 mg/dl by the Auto-Analyzer and 229.8 mg/dl by the Autochemist.

Detection of the occurrence of breast cancer.—Cases of breast cancer in this group of women were identified from two sources. The first source was a computer file of all KFHP hospital discharges in northern California from 1971 through 1977. This file included patients discharged from KFHP hospitals in the five San Francisco Bay area counties (Alameda, San Francisco, Marin, Contra Costa, and San Mateo) plus Solano, Sacramento, and Santa Clara counties. Although only the first three primary discharge diagnoses were sought, it would be unlikely for any newly developed cancer of the breast to be missed by this method of ascertainment. The second source was a manual review of disease indexes for the years 1960 through 1970 in all KFHP hospitals in northern California. The California Tumor Registry, which covers only the five San Francisco Bay area counties and which overlaps the KFHP files for the years 1969 through 1977, provided a partial check on the completeness of the KFHP records. When we cross-matched the

KFHP hospital discharge file with the tumor registry file for KFHP members, we detected only 26 (2.5%) additional documented breast cancers.

All medical records of persons with breast cancer detected in this manner were reviewed to confirm the diagnosis and record the date of diagnosis. A file of all detected breast cancer cases from the years 1960 through 1977 was created and cross-matched with the file of women who had had an MHC during the period 1964 through 1972. All persons with a diagnosis of breast cancer before and up to 6 months after their first MHC were excluded, leaving a cohort of 95,179 women who were 15 years and older without a history of breast cancer and who had had an MHC. From 1964 to December 31, 1977, breast cancer developed in 1,035 of these women.

Determination of the duration of follow-up.—Because of unequal follow-up periods, we used person-years of exposure to determine rates. Follow-up always began at the date of a woman's first MHC and ended with the diagnosis of cancer, the end of the study, or when she was lost to follow-up due to termination of membership. If she terminated membership and there was no termination date on file, loss to follow-up was estimated to occur at a point halfway between the year of the last MHC and December 31, 1977. This method for estimating the end of follow-up was required for 19.2% of the subjects.

If a woman left the KFHP and subsequently developed breast cancer, this breast cancer would not have been detected; however, she was not considered at risk after leaving the KFHP. If she had gone to an outside facility for diagnosis and treatment while still a KFHP member, she would probably have had the diagnosis recorded on her next KFHP hospitalization. We therefore were confident that we had reasonably complete ascertainment of breast cancers that occurred while women were still members of the KFHP.

Statistical analysis.—Breast cancer incidence rates were calculated in relation to each independent variable of interest. Rates were age adjusted by the direct method with the use of total population as the standard. A standard z-statistic was used for two-sided tests of significance between the rates for dichotomous variables with the use of the variance of the age-adjusted rate given by Chiang (*10*). For ordered qualitative variables and continuous variables, grouped into ordered categories, possible trends were examined by the calculation of the Mantel extension chi-square and the slope coefficient (*11*).

To ensure that some relation between cholesterol and breast cancer was not obscured by confounding factors, we performed multivariate analysis employing Cox's proportional hazards model (*12*) programmed for the Statistical Analysis System (*13*). This procedure allows for the differing length of follow-up of the subjects. Only women at least 30 years of age were included in this analysis, since risk is so low below that age. The 8% of women who were neither white nor black were excluded. Moreover, because of the unacceptable number of unknown values, women who had their first MHC in 1964 were eliminated from these analyses. After the above exclusions, 50,000 women without breast cancer remained in the cohort. Because the additional statistical benefit of including more than about 5 noncases to 1 case is small (*14*), we randomly selected women without breast cancer in a ratio of 5:1 to cases. We excluded 3% of the cohort with more than three unknown values, which left 714 cases and 3,675 noncases for the multivariate analysis.

Multivariate analysis was also performed by multiple logistic regression analysis as programmed by Brand and Sholtz [described in Rosenman et al. (*15*)]. Although this analysis does not take length of follow-up into account, results of the two multivariate analyses were essentially identical; only those based on the Cox model are presented.

The extremely large number of breast cancer cases in this study make it highly probable that an association with serum cholesterol would be observed and be statistically significant at the 0.05 level, if such an association truly existed. Of 1,035 breast cancer cases, 948 were among 87,354 women (869,602 years of follow-up) with known age and cholesterol values. When cholesterol concentrations are separated into low (<220 mg/dl) and high (≥220 mg/dl) levels, there is a 75% chance of detecting an RR as small as 1.2 and an almost certain probability (99.9%) of detecting an RR of 1.4 or larger. Although there is no direct way to calculate the statistical power of our multivariate analysis, 714 breast cancer cases is a very large number in comparison to the number in other cohort studies.

RESULTS

Incidence of breast cancer.—Breast cancer incidence in the entire cohort was 1.38/1,000 person-years of follow-up. Age-specific rates (table 1) revealed a direct relation to age, with the highest rates in the group over 70 years of age. The mean person-years of follow-up was 7.9. The age-specific rates were similar to those reported by the TNCS for the San Francisco SMSA (*16*).

Serum lipids.—The incidence of breast cancer was neither directly nor inversely associated with the level of serum cholesterol measured at the first MHC. When cholesterol concentrations were separated into low (<220 mg/dl) and high (≥220 mg/dl) levels, a slight and nonsignificant negative association was noted for the age-adjusted rates (1.39/1,000 person-yr vs. 1.35/1,000 person-yr, respectively). When women were classified by quartiles of cholesterol

[b] Figures are based on cohort of 87,354 women with known cholesterol values.

level, the hypothesized trend of increasing incidence with increasing cholesterol was not seen (table 2). Instead, rates decreased from the lowest to the 220- to 224-mg/dl level and increased for the ≥245-mg/dl level. The same general pattern was seen for β-lipoprotein and total lipids. In 10-year age-specific groups, breast cancer incidence showed no consistent trend for any of the three lipid measures, indicating that no relation existed for women in either the premenopausal or postmenopausal age groups. The subset of women who had β-lipoprotein and total lipids measured at their first MHC during the period from 1969 through 1972 had a total incidence higher than that in the total cohort (1.79 and 1.78/1,000 person-yr, respectively). This difference is only partially explained by the greater age of this subcohort.

Known risk factors.—The incidence of breast cancer was found to increase with the highest educational level attained ($P=0.001$), which we used as a measure of socioeconomic status. Breast cancer was more common among white women (1.46/1,000 person-yr) than black women (0.98/1,000 person-yr, $P<0.001$) or Asian women (0.87/1,000 person-yr, $P=0.002$). We did not have specific information about breast cancer in family members, but breast cancer did occur more commonly in women with a history of any cancer in mothers or sisters ($P=0.045$). We noted a slightly increased risk of breast cancer among women never married versus those ever married, but the difference was not significant.

Breast cancer incidence generally decreased with increasing age of menarche after age 13 years ($P=0.008$). Women with menopause before age 40 years had substantially less risk of breast cancer than those with later menopause. Rates generally increased with menopausal age ($P=0.016$), but the trend was not steady. We did not have data on the age at first pregnancy but, as expected, parity was inversely related to breast cancer risk ($P=0.012$).

We found an inverted U-shaped relation between the Quetelet index of body mass (weight/height^2 × 100) and breast cancer rates. Breast cancer was less common in the most lean and the most obese than in the women in the middle range in this cohort. Daily alcohol consumption was directly related to breast cancer risk in an uneven trend from no drinks through one to two and three to five drinks to over five drinks per day ($P=0.016$). The rate was nonsignificantly higher in smokers than in nonsmokers but was significantly higher in ex-smokers than current smokers ($P=0.008$).

A history of at least one chest X-ray examination and a history of nipple discharge were not significantly related to breast cancer rates. However, the rates were higher in women who had a history of any breast operation ($P<0.001$) and in those who had any abnormality on mammography ($P=0.043$). The last two variables probably reflect the presence of benign breast disease. The use of birth control pills, of pills to control menstrual periods, and of any "hormones" in the year before the MHC had no significant relation to breast cancer rates.

Multivariate.—When 10 covariables and breast cancer were analyzed together, the results (table 3) still failed to show any significant relation between cholesterol and breast cancer. That is, no hidden association of cholesterol and breast cancer incidence was uncovered by simultaneous consideration of nine other variables that either were known risk factors or (in the case of smoking) were associated with breast cancer in our study population in the univariate analysis. The variables with most effect in this analysis can be assessed by a comparison of the adjusted RR and the significance probabilities. Thus being of older age, of lower

TABLE 3.—*Results of multivariate analysis of risk factors for breast cancer in women age 30 years and over*

Variable	Significance, *P*	Adjusted RR	95% confidence limits	RR associated with:
Age	<0.001	1.28	1.15, 1.41	10-yr increase
Parity	0.003	0.93	0.89, 0.98	Each additional birth
Race	0.008	1.45	1.10, 1.90	White vs. black
Menopause	0.018	0.76	0.61, 0.95	Yes vs. no at MHC
Age at menarche	0.032	0.95	0.90, 0.99	1-yr increase
Education	0.144	1.05	0.98, 1.11	Completion increased one level[a]
Quetelet index	0.194	1.07	0.96, 1.20	One unit increase, pounds/inch^2 × 100
Smoker	0.234	1.10	0.94, 1.29	Current or ex-smoker vs. never smoked
Cholesterol	0.337	1.01	0.99, 1.03	10-mg/dl increase
Alcohol	0.639	0.96	0.80, 1.14	Current use, yes vs. no

parity, white, premenopausal (at any given age), and of a younger age at menarche were significantly related to breast cancer with a probability of 5% or less that the association occurred by chance. The level of highest education, body mass, smoking status, alcohol consumption, and cholesterol level were not significantly associated with breast cancer. The same analysis was performed for women according to whether they said they were premenopausal or postmenopausal at the time of their first MHC. In both analyses, cholesterol remained unrelated to breast cancer incidence with the adjusted RR for an increase of 10 mg/dl close to 1.0 for both groups.

DISCUSSION

The principal finding of this study was that no direct relation exists between the result of a single serum cholesterol determination and the subsequent development of breast cancer in women. Similarly, no direct relation was seen between total serum lipids or β-lipoprotein, which is highly correlated with cholesterol, and breast cancer in this cohort. This conclusion was based on the absence of any observed dose-response relation between women characterized by the quartile of their blood lipid levels and their subsequent development of breast cancer. The meaning of the pattern of observed rates is not known and is compatible with either random fluctuation in rates or increased risk for women at either extreme of serum cholesterol level. A simple dichotomization of cholesterol revealed a small and nonsignificant negative association of cholesterol level with breast cancer. Multivariate analysis indicated no relation between serum cholesterol and breast cancer with simultaneous consideration of nine other possible risk factors.

Our findings are consistent with previous reports of higher breast cancer risk with increasing age (*3*, *17*), with higher educational level representing socioeconomic status (*2*), in white versus black or yellow races (*17*), with reproductive variables of lower age of menarche and higher age of menopause, with lower parity (*3*, *17*), with indicators of benign breast disease (*17*), and in women who have never married (*16*). We found no increased risk in women who had taken estrogens to control menstrual periods or to control birth (*17*). As a proxy for family history of breast cancer (*17*), we found that there was also increased risk with a family history of any cancer in mothers and sisters. We did not confirm previous reports on increased risk in women with greater body mass (*18*), although this relation has not been consistently found (*17*).

Univariate analysis suggested that alcohol consumption was associated with increased risk of breast cancer. This same relation has been noted by Williams and Horm (*19*) in a case-control study based on the TNCS, and a possible etiologic role for alcohol has been discussed by Williams (*20*). In our multivariate analysis where the alcohol variable was dichotomized, we did not confirm an independent effect of alcohol. Analyses are under way to examine this relation further.

Current smokers were at slightly but not significantly greater risk than nonsmokers. However, ex-smokers had a significantly greater risk than either nonsmokers or current smokers, possibly related to differences in socioeconomic status (*21*).

The results of the present study are consistent with and enlarge upon other recent studies of the relation of serum cholesterol to subsequent development of breast cancer in follow-up studies. Kark and co-workers (*22*) reported a slight negative association between serum cholesterol and breast cancer in a prospective study in Evans County, Georgia. However, their results were based on only 7 cases of breast cancer. Williams and co-workers (*23*) found a small but insignificant negative correlation between serum cholesterol and breast cancer in the Framingham study based on 75 breast cancer cases that occurred over an 18-year period; in Tecumseh, Michigan, Higgins found no relation between base-line cholesterol or triglyceride levels and the incidence of breast cancer that developed in 65 women over a 13- to 20-year period (Higgins M: Unpublished data).

Case-control studies of women *after* the diagnosis of breast cancer have yielded conflicting results (*24–29*), although most suggest that serum lipids (*24–27*) and urinary cholesterol (*28*) are higher in women with breast cancer than in various other groups. Concerning the possible etiologic relation of serum cholesterol to cancer, however, these studies have shortcomings in their choice of controls and their inability to determine whether the high cholesterol level or the cancer was primary. Even with prospective studies that determine cholesterol before the diagnosis of cancer, the metabolic influence of subclinical cancer on cholesterol must be considered, since investigators have found that the inverse association between serum cholesterol and cancer mortality may hold for only 2–7 years of follow-up (*30*, *31*). That is, subclinical cancer may have some effect on cholesterol level. Because, in the present study, the mean time to diagnosis of breast cancer was 7.9 years (range, 1–13 yr) and in the Framingham study cancer incidence was measured over an 18-year period, we would expect this potential effect to be minimal. However, further work that examines time to diagnosis in the relation of serum cholesterol and cancer is needed.

Although it does not disprove the hypothesis that high dietary fat is an etiologic factor in breast cancer, our study adds to a growing body of negative data. Hill and co-workers (*32*) as well as Wynder and associates (*4*) have proposed plausible biological explanations of how dietary fat might be tied to breast cancer, but prospective human epidemiologic evidence from Evans County (*22*), Framingham (*23*), Tecumseh (Higgins M: Unpublished data, 1980), and the current KFHP population does not support a role for serum cholesterol in this disease. The data by Rost and co-workers from the Lipid Research Clinic in Iowa (*33*) suggest a conflicting finding, but details of this study are not yet published. It should also be appreciated that the animal work by Carroll and Khor (*7*) showed an increasing incidence of mammary tumors with increasing vegetable fats rather than animal fats in the diet.

The relation between cancer and serum cholesterol that seems better supported is an inverse one for all cancers together and for colon cancer in men specifically. The analyses of this relation in the large prospective studies of coronary heart disease (*23*, *30*, *34–37*) are limited in that they usually deal only with men and that they include insufficient cases of the less common cancers to draw reliable conclusions.

The inverse overall association of cholesterol and cancer remains unexplained. The effect of competing mortality from diseases in which cholesterol is a risk factor (e.g., coronary heart disease) has been suggested (*23*). However, Kark and co-workers (*22*) excluded persons who died of cardiovascular disease and found that the inverse relationship was enhanced for men but not for women. Other hypotheses that consider increased membrane permeability to carcinogens, reduced ability of lymphocytes to detect and kill tumor cells, and other pathophysical mechanisms in which cholesterol may play a role (*23*) need further study.

In conclusion, we were unable to find any direct association between serum cholesterol and breast cancer incidence in a cohort of over 95,000 women in the KFHP. Similarly, in about one-fourth of this cohort, we found no relation of serum β-lipoprotein or total lipids to breast cancer. The lack of association between serum cholesterol and breast cancer was evident throughout both univariate and multivariate analyses, in which most other known risk factors for breast cancer behaved as expected on the basis of previous knowledge. Our findings suggest that dietary fat intake, if related to increased breast cancer risk, is related through some other metabolic pathway than through an elevation of the serum lipids measured in this study.

Carcinomas of the Cervix and Corpus Uteri in Humans: Stage-Dependent Blood Levels of Substance(s) Immunologically Cross-Reactive With Insulin [1,2]

K. Pavelić, [3] **M. Bolanča,** [4] **N. Veček,** [4] **J. Pavelić,** [3] **T. Marotti,** [3] *and* **S. Vuk-Pavlović** [5]

ABSTRACT—Inasmuch as the elevated levels of substance(s) immunologically cross-reactive with insulin (SICRI) in a diabetic woman with carcinoma of the corpus uteri decreased following the surgical removal of the uterus and ovaries, 80 women with cervical carcinomas of various stages and 70 women with carcinomas of the corpus uteri of various stages were screened for the levels of SICRI and C-peptide. The levels of SICRI in the second, third, and fourth stages of the cancers were elevated (up to six times above the normal levels of immunoreactive insulin) and stage-dependent. The levels of C-peptide, which are related to the insulin-secreting activity of pancreatic β-cells, were normal and independent of the stage of cancer.—JNCI 1982; 68:891–894.

Recently, we screened patients with Hodgkin's (*1*) and non-Hodgkin's lymphomas (Pavelić K, Vuk-Pavlović S: Submitted for publication) for the levels of SICRI and of C-peptide in non-Hodgkin's lymphoma. We found that the levels of SICRI in blood depend on the stage of Hodgkin's disease and are significantly higher in the relapse phase than in the remission phase of non-Hodgkin's lymphomas [(*1*); Pavelić K, Vuk-Pavlović S: Submitted for publication]. Our preliminary results with mice suggest that SICRI is produced by the tumors themselves and that it stimulates tumor proliferation (*2*). Therefore, the ability of a clinician to control and modulate blood levels of SICRI in cancers might be relevant.

We found high levels of SICRI in the blood and tumor tissue in a diabetic patient with carcinoma of the corpus uteri. After surgery SICRI decreased sharply, but glucose levels remained unaffected. This finding precipitated the screening of SICRI in the blood of 150 women with cervical carcinomas or carcinomas of the corpus uteri, i.e., solid tumors. The mean levels of blood SICRI were elevated in all stages of the disease and were higher in the patients with a more progressive disease.

MATERIALS AND METHODS

Blood was drawn from hospitalized patients before breakfast. It was immediately refrigerated at 4°C, and the clot was removed by centrifugation. Glucose levels in sera were measured immediately thereafter according to (*3*). The levels of SICRI in sera, in trypsinized tumor cells, and in normal uterine and renal cells (*4*) were determined by the insulin-specific RIA (*5*) with the use of radioiodinated porcine and crystalline rat insulin standards (Sorin, Sallugia, Italy). The levels of C-peptide were measured by the RIA (Byk-Mallinckrodt, Dietzenbach, Federal Republic of Germany) according to (*6*). If RIA determinations were not performed on the same day that the blood was drawn, sera were frozen immediately after clot removal and kept at −20°C (not longer than 15 days). On several occasions, RIA determinations in fresh control sera were compared with the respective values obtained with the same sera frozen for 15 days and no difference was noted.

The full RIA titration of SICRI was performed and the dilution–activity lines were parallel to those obtained with the insulin standard in the sera of 2 patients.

The results were statistically evaluated by the χ^2 test with the use of a computer program (*7*).

RESULTS

Patient #1 (76 yr old) was admitted to the clinic on October 23, 1979, for postmenopausal uterine bleeding lasting 5 months. For the last 20 years, she had suffered from hypertension. She had geriatric diabetes, which was controlled by diet only, 1 year before the admission to the hospital. The histologic examination of the material obtained by a fractional curettage demonstrated an adenocarcinoma of the corporeal endometrium. Phytohemagglutinin-stimulated blastic transformation of the patient's lymphocytes (*8*) yielded an index of 29, in contrast to 80 found in healthy controls. (These indices are the ratios of [^{3}H]thymidine incorporated by the phytohemagglutinin-stimulated cells vs. those incorporated by the nonstimulated cells.) The granulocyte inhibition test (*9*) to tuberculin (purified protein derivative) gave an index of 140 in comparison to 80 in normal controls. The concentration of IgM in blood was 640 mg/liter (normal values: 700–2,800); the concentrations of IgG and IgA were normal. These results together with the histologic findings prompted surgical removal of the uterus and adnexa.

The uterus was slightly enlarged, but there were no macroscopic changes in the ovaries. Metastases were not found in the abdominal cavity and organs therein. The histopathologic examination of the uterus confirmed the preoperative diagnosis of an endometrial adenocarcinoma.

ABBREVIATIONS USED: RIA=radioimmunoassay(s); SICRI=substance(s) immunologically cross-reactive with insulin.

TEXT-FIGURE 1.—Levels of SICRI (▨) and glucose (☐) in blood of diabetic patient #1 with adenocarcinoma of corpus uteri, before and after surgery. Blood was drawn before breakfast.

The tumor penetrated the myometrium to a depth of 8 mm. A fortnight later a dose of 2,500 rad of radioactive cesium was applied for 48 hours in the vagina. Six months after therapy the patient felt well, and the gynecologic examination showed no pathologic changes. The immune status was normal.

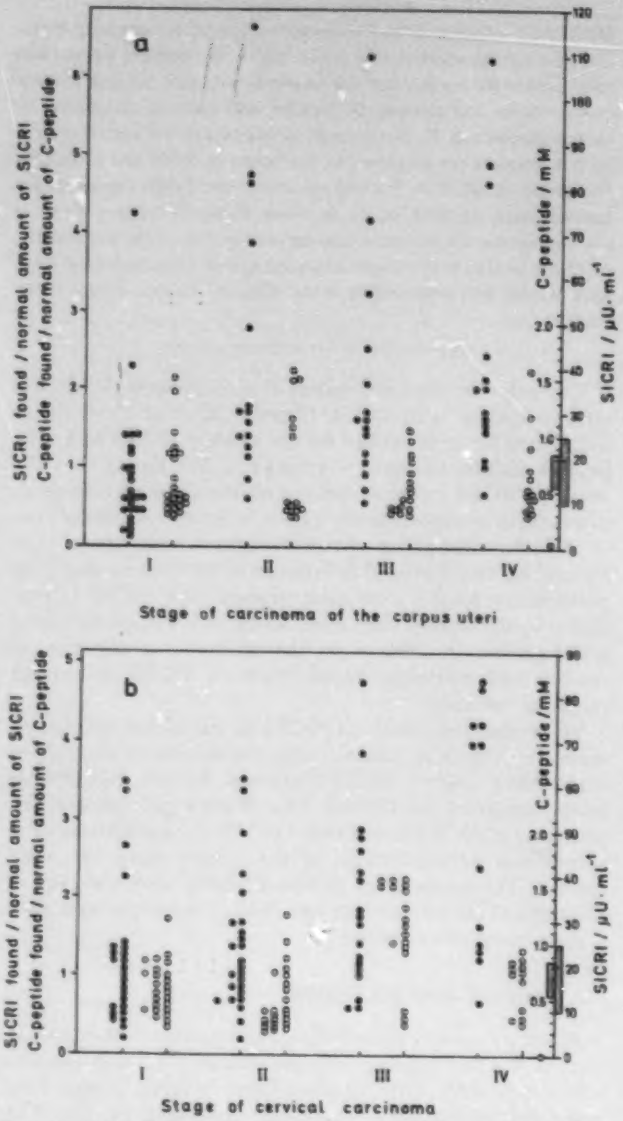
The serum levels of SICRI and glucose (text-fig. 1) were determined on two occasions before and three occasions after surgery. As can be seen in text-figure 1, high preoperative levels of SICRI, determined by insulin-specific RIA, decreased dramatically following surgical treatment. The elevated preoperative blood glucose levels, however, were not influenced significantly by the sharp decrease of SICRI showing that this tumor-associated substance(s), found in the diabetic patient, does not exert the same physiologic effects as insulin.

We incubated the patient's serum with [^{125}I]insulin for 3 days and chromatographed it on a Sephadex G-50 column (1×60 cm) equilibrated with water (*10*). A single peak at V_e:V_t=0.53 was obtained indicating that during incubation degradation of radioiodinated insulin did not occur. (V_e and V_t denote the elution volume and the total volume of the gel measured by ^{125}I-labeled Na, respectively.) An identically treated sample of normal serum also gave a single peak with the ratio V_e:V_t=0.58, showing that the apparent molecular

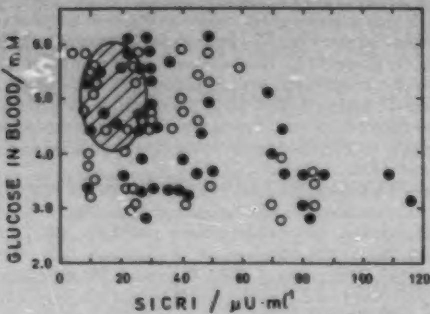
TABLE 1.—*Significance of differences between blood SICRI levels in patients with various stages of cervical carcinomas and carcinomas of the corpus uteri evaluated by the χ^2 test*[a]

Stage of cervical carcinoma or carcinoma of the corpus uteri	Significance of difference		
	IV	III	II
I	*P*<0.01	*P*<0.01	NS
II	*P*<0.01	NS	
III	NS		

[a] Data displayed in text-fig. 2a (carcinomas of corpus uteri) and text-fig. 2b (cervical carcinomas) were evaluated separately; the significances of the differences between stages of cancer were the same in both groups. NS=not significant.



TEXT-FIGURE 2.—Preoperative levels of SICRI (●) and C-peptide (○) in the blood of 70 patients with carcinomas of the corpus uteri (a) and 80 patients with cervical carcinomas (b). *Left ordinate* displays the normalized scale both for SICRI and C-peptide. *Scales on the right ordinate* display the absolute concentrations where the *shaded areas* denote the mean ranges of minimal and maximal values of C-peptide and insulin detected by the respective RIA in 200 normal persons. Blood was drawn before breakfast. The ages of 131 of 150 patients were between 50 and 80 yr. Two were older (the oldest being 84 yr) and 17 younger (the youngest being 20 yr). No correlation was found between the patients' ages and blood levels of SICRI and C-peptide.



TEXT-FIGURE 3.—Correlation of levels of SICRI and glucose in the blood of 82 patients with carcinomas of the corpus uteri (●) and cervical carcinomas (○). Only the patients from text-fig. 2 for whom both SICRI and glucose were measured in the same sample of blood are represented. *Data points within the shaded area* represent patients with normal levels of both SICRI and glucose.

weight of SICRI is not altered by binding to other macromolecules.

We determined the intracellular SICRI levels in the tumor itself and in pieces of normal uteri and normal kidneys as references. SICRI (35 μU/g of tumor tissue) was compared with 1.5±0.5 and 0.7±0.5 μU/g found in the uteri and in the kidneys, respectively.

These results prompted a survey of 70 nondiabetic patients with various stages of carcinomas of the corpus uteri and 80 nondiabetic patients with various stages of cervical carcinomas for the levels of SICRI and of C-peptide. This peptide (a cleaved part of the proinsulin molecule) reflects the blood levels of insulin. The results are presented in text-figure 2, and the levels of significance of the differences between groups are tabulated in table 1. While the differences in SICRI levels were significant between stages I and III, I and IV, and II and IV in both cancers, there was no difference between the corresponding C-peptide levels (text-fig. 2).

For 82 patients we have data on the levels of glucose in the same samples of blood in which SICRI and C-peptide were measured. The correlation of SICRI and blood glucose is shown in text-figure 3.

DISCUSSION

From the data presented in text-figures 1–3, we conclude that: 1) Blood SICRI levels are not paralleled by the C-peptide levels; 2) SICRI is closely associated with and probably secreted by the tumor, since it is high in the blood of a diabetic tumor-bearing patient before surgery and decreases following surgery and since its intracellular levels are more than 20 times higher in the tumor than in the normal uteri; and 3) only very high levels of SICRI induce hypoglycemia (text-fig. 3). Moreover, the present results demonstrate elevated and stage-dependent levels of SICRI in patients with cervical carcinomas and carcinomas of the corpus uteri as detected by RIA specific for pancreatic insulin (text-fig. 2); i.e., the more progressive the disease, the higher the blood level of SICRI.

Similarly, elevated levels of insulin-like substances have also been noted in patients with fibrosarcoma (*11*), adenocarcinoma (*12*), cervical carcinoma where hypoglycemia also was noticed (*4*), renal adenocarcinoma (*13*), Hodgkin's disease (*1*), and non-Hodgkin's lymphoma (Pavelić K, Vuk-Pavlović S: Submitted for publication). Also, a large body of evidence for the existence and function of tumor-associated SICRI has been accumulated in our work with murine tumors under a variety of experimental in vivo (*2*) and in vitro (*14*) conditions. From these experiments, we know that SICRI-secreting tumors grow faster (*2, 15, 16*). There are, however, tumors not associated with elevated SICRI. Recently, we screened 24 patients with tumors of the ovaries and found no change in the blood-immunoreactive insulin levels (Sekelji B, Grgurević M, Pavelić K: Unpublished data).

The present findings raise the question about the molecular identity and origin of SICRI associated with tumors. The results of the Sephadex G-50 gel filtration of sera preincubated with the radioiodinated insulin (*see* "Results") demonstrate that RIA-detectable entities are neither the products of insulin degradation nor insulin bound to macromolecular carriers. Also, SICRI most probably is secreted by the tumor tissue, at least in diabetic tumor-bearing patients [(*13*); this work] and in mice with alloxan-induced diabetes (*2*). This SICRI secretion by the tumor tissue has been proved in vitro directly in murine mammary aplastic carcinoma (*14*).

Concentrations of SICRI and C-peptide in peripheral blood are correlated (*17*) and result from the balance of secretion rates and respective clearance rates. It is known that the normal clearance rates of insulin are larger than those of C-peptide (*17*). From a study of nondiabetic, nonobese patients, Horwitz et al. (*17*) obtained the relation [insulin] = 0.39 [C-peptide] − 0.78 in the peripheral blood. By use of this empirical equation, it is easy to show that under normal conditions the concentrations of peripheral C-peptide will always rise faster than those of pancreatic insulin.

In the present paper, we demonstrate the opposite effect; i.e., peripheral levels of SICRI rise much faster than C-peptide levels and SICRI concentrations depend on the stage of cancer, whereas those of C-peptide do not (text-fig. 2). Thus SICRI is probably not generated by proinsulin splitting. Inasmuch as the high level of SICRI in blood is not necessarily accompanied by hypoglycemia (text-fig. 3), it might be identical to proinsulin; the increased levels of this molecule, however, would also increase the level of RIA-detectable C-peptide (*18*).

Theoretically, there are various explanations for the elevated levels of SICRI in diabetics and nondiabetics where the corresponding changes of C-peptide levels do not take place. One is that insulin has a clearance rate much lower than normal. However, insulin turnover rates in insulin-dependent tumors are higher than normal (*19*), which refutes this idea.

The alternative explanation is based on the assumption that tumor tissue secretes SICRI. Several facts support this hypothesis: 1) high preoperative and low postoperative levels of SICRI in diabetic patient #1; 2) the lack of correlation of SICRI and blood sugar levels in patient #1 (text-fig. 1) and the apparently weak correlation in a population of nondiabetic patients (text-fig. 3), showing that the elevated levels of SICRI are not necessarily followed by hypoglycemia; and 3) the lack of correlation between the stage of tumor-dependent SICRI levels and the independent levels of C-peptide.

The idea of ectopic production of insulin and insulin-like molecules is theoretically less unfamiliar if one knows that molecules functionally and immunologically related to insulin are found in various cells and tissues, even in the microbial world [(*10*) and references therein].

A Quest for the Mechanism of "Spontaneous" Malignant Transformation in Culture With Associated Advances in Culture Technology[1,2]

Katherine K. Sanford[3] *and* **Virginia J. Evans**[4]

ABSTRACT—The discovery of "spontaneous" malignant transformation of mouse cells in culture raised questions answerable only by obtaining a better control of culture conditions through technologic advances. One of these advances was the introduction of cellophane and later glass as a substrate to replace the plasma clot matrix, widely used in tissue culture at that time. Removal of cells from plasma clot and culture under cellophane or on glass not only increased cell yield but also allowed the manipulation of individual cells in suspension. Other advances included the design and technology of three-dimensional substrate cultures, the establishment for the first time of clonal cell populations from single isolated cells, the development of instrumentation and quantitative techniques for measuring cell proliferation, the introduction of the suspension culture of cells of "fixed tissue" origin, and the formulation of serum-free, antibiotic-free, chemically characterized culture media that could support the continuous proliferation of numerous cell lines from different tissues and species. These technologic advances promoted the application of microbial techniques to vertebrate tissue cells, marked the beginning of modern quantitative cell culture, and provided the tools for recent developments in virology, vaccine production, genetics, molecular biology, and other areas of biomedical research. These technologic advances were associated with a quest for an explanation of spontaneous malignant transformation. In this quest it was found that normal tissue cells of various rodent species after prolonged culture in the absence of added carcinogens or viruses and even in serum-free, chemically defined medium undergo malignant transformation. Certain differences between the normal cell and its malignant derivative were identified, and their reliability as in vitro criteria of malignancy was shown. Certain observations support the hypothesis that aberrant methylation of nucleic acids may be a chemical event in carcinogenesis, and methyltransferases were discovered in all RNA retroviruses examined. Three environmental agents were found to enhance or induce malignant transformation: the type of serum used, molecular oxygen, and repeated exposure to low-intensity fluorescent light. All three agents produce chromosomal DNA damage. Experimental results indicate that the DNA damage produced by light results directly or indirectly from the intracellular generation of hydrogen peroxide and/or the derivative free hydroxyl radical. Thus the malignant transformation of rodent cells is not spontaneous but is induced by specific environmental agents that produce chromosomal DNA damage. The progression to malignancy in mouse cells and the susceptibility of human cells to malignant transformation appear to be associated with an impaired capacity to repair the DNA damage produced by these environmental agents.—JNCI 1982; 68:895–913.

The discovery years ago of the "spontaneous" neoplastic or malignant transformation of normal cells in culture raised a number of questions fundamental to the problem of cancer; this discovery led to a long quest for elucidation of mechanisms, possible contributing factors, and associated cellular lesions. An important element in this quest was the need to fashion tissue culture into a precise quantitative tool. One of the outstanding pioneers in cell culture was Wilton R. Earle who, with his co-workers in the Tissue Culture Section of NCI, advanced cell culture technology and increased our knowledge of malignant transformation. The Tissue Culture Section was initially headed by Dr. Earle and subsequently by Dr. Virginia J. Evans and later by Dr. Katherine K. Sanford. In this report, we summarize the activities of this Section and have attached a bibliography to document the contributions of the individual members of the staff and collaborating scientists.

ADVANCES IN CELL CULTURE TECHNOLOGY

Before his studies at NCI, Dr. Earle had been attempting to control the environment of mammalian cells in culture. Among his contributions, he showed that short exposure of leukocytes or chick fibroblasts to light in the visible range caused cell degeneration, especially in the presence of photosensitizing substances from red blood cells (*1–4*); improved the techniques of both hanging-drop cover slip and Carrel flask culture by introducing means for adjustment of pH, oxygen, and carbon dioxide (*5, 6*); devised a simple press for mincing soft tissues (*7*); formulated an isotonic balanced saline solution, Earle's saline, (*6*); and introduced the use of HS as a supplement to chick embryo extract and chicken plasma clot and showed that this medium could support the continued proliferation of epithelial cells from rat mammary carcinoma (*8–10*). He found that thin, strip-shaped explants for both initiation and subculture provided an increased cell yield as compared with the 1- to 2-mm^2 explant in use at that time (*11*). An approximately direct relationship between explant size and area of outgrowth was observed, as was a minimal size that failed to grow because of some factor(s) other than exhaustion of the medium (*12*).

Replacement of the Plasma Clot and Development of Three-Dimensional Mass Cultures

Our discovery of malignant transformation of mouse cells in culture raised a question as to whether the transformation is spontaneous, i.e., resulting from intrinsic instability of cells or induced by some environmental factor(s). Therefore, research efforts were directed toward developing a chemically characterized culture medium that eliminated any unidentified chemical carcinogens, hormones, or viruses which might be introduced through the biologic culture medium of chick embryo extract, HS, and chicken plasma that were used in all of our experiments. The chemically undefined plasma clot was replaced with a sheet of perforated cellophane, an inert defined material. The cellophane sheet provided a luxuriance of cell growth superior to that obtained in plasma clot or glass-substrate explant cultures (*13–17*). Cultures of increasingly larger surface area were grown (*18*), including cell types of biomedical importance such as human skin epithelium, bone, and cornea for preservation and transplantation (*19–29*), human endocrine tissue for hormone production (*30*), and human cells in nonhuman serum for potential use in vaccine production (*31*). The cellophane sheet also allowed the ready dispersal of cells for development of single cell clones and cell suspensions that could be inoculated on glass substrate and quantified for growth experiments (*32, 33*). By use of a massive inoculum, dispersed cells from chick embryo tissue could be seeded onto glass flasks (*33*). Two types of three-dimensional substrate cultures were developed: one with multifolded perforated cellophane sheets as substrate and the other with pyrex glass helices through the interstices of which the nutrient fluid was mechanically circulated (*34*). These three-dimensional substrate cultures yielded even greater amounts of living cells than were produced on two-dimensional substrates and were forerunners of present-day commercial vessels used for bulk production of substrate-dependent cells (*35*).

Development of a Cloning Procedure

Purity of cell type can be attained only by the isolation and growth of single tissue cells. In the late 1940's, the inability to grow single cells resulted from inadequate culture media and incomplete knowledge of the physiologic requirements of small numbers of cells. Whereas a large clump of tissue cells could adapt a reasonable volume of culture medium, one cell grown in an identical volume was unable to adjust the fluid sufficiently for survival and proliferation. A procedure was therefore developed for isolating single cells in glass capillary tube segments by which the rapid diffusion of metabolites was restricted and the culture medium was thus conditioned. Under these conditions, single isolated mammalian tissue cells for the first time were grown into clonal populations (*36*). The first cloned line NCTC 929L, derived from strain L, is widely used in many areas of research. This capillary cloning procedure, later modified and simplified (*37, 38*), provides greater assurance than plating methods that the clonal population is indeed derived from one cell. To preclude possible contamination of clones with cells from chick embryo extract, a procedure was developed for extract filtration (*39*). The capillary cloning procedure was successfully applied to many other cell types of chicken, mouse, or human origin such as cells from the liver, the parotid gland, subcutaneous connective tissue, or mammary carcinoma (*40–46*). This precise cloning technique led to the development of other cloning procedures and the application of bacteriologic plating methods to mammalian tissue cells.

Quantification of Cell Proliferation and Development of Suspension Cultures

For further development of a chemically defined culture medium, a quantitative growth assay was required to evaluate nutritional factors influencing cell proliferation (*47*). Methods and instrumentation were designed for the preparation of replicate cultures from sieved, mechanically stirred cell suspensions (*48–51*) and for quantification of proliferation rates by enumeration of isolated cell nuclei (*52*). So that cells would not be lost during quantitative nutrient fluid renewal, a new culture vessel was designed, the T-flask, with a conical tip into which dislodged cells could settle during slow centrifugation (*53*). A modification of this flask for use with high-resolution photomicrography was subsequently developed (*54*). Rubber stoppers for these flasks, shown to be toxic to cells and perhaps even carcinogenic, were replaced with silicone stoppers designed by Earle and fabricated to his specifications (*55*).

Studies on the influence of inoculum size showed that cell population density per unit volume of culture medium is a major factor affecting rates of cell proliferation (*56*). Established cell lines such as NCTC clone 929L were found to proliferate at equivalent rates on glass and cellophane substrate (*57*). The influence of motion of the medium on cell proliferation was then explored by a comprehensive study of rate of roller tube rotation on cell yield (*58*). At the highest speed of rotation, 2,400 revolutions per hour, individual cells were free floating and proliferating at a high rate. This study demonstrated for the first time that "fixed-tissue" mammalian cells that have undergone malignant transformation can proliferate as a free-floating suspension in rapidly agitated fluid medium (*59*). The Brunswick-type rotary mechanical shaker designed for the antibiotics industry was then redesigned and successfully used for large-scale, batch-type culture of mammalian cells in suspension (*60–62*). The dynamics of cell proliferation in the suspension culture, glycolytic rates under different culture conditions, and chemical alterations of the medium were analyzed in efforts to devise culture conditions that would enhance cell yield (*62–66*). From these batch-type, suspension cultures and the large-scale, surface substrate cultures, adequate numbers of cells were obtained for analyses of biochemical properties including enzyme patterns. These characterizations were essential for identifying the type of cells in culture and for determining the extent to which the cells maintain differentiated function and structure during continuous culture.

Development of Chemically Defined Culture Media

By 1950, two chemically defined media had been reported that supported outgrowth and limited survival of avian embryonic tissue. However, in neither of these did mammalian NCTC clone 929L cells proliferate as determined by our quantitative assay (*67*). In our development of a chemically defined medium, two approaches were used: analytic and synthetic combined with depletion techniques (*68*). NCTC clone 929L served as the assay cells. Both the serum and embryo extract components of the medium were fractionated separately and analyzed chemically (*69–71*). Two fractions, the ultrafiltrate of embryo extract and the large molecular protein fraction of HS, together yielded cell numbers approaching those obtained with complete medium (*72*). Further fractionation of the serum proteins yielded globulin fractions I and III that could be substituted for the large molecular fraction of HS in a protein-free basal medium (*73*). Because all protein fractions stimulated growth, it appeared that the proteins might be serving a physical protective role in the medium; therefore, some large molecular polymers were tested in a protein-free basal medium, but none of these supported maximum growth (*74*). During the course of these analytic studies, whole-egg ultrafiltrate was found to be an effective substitute for chick embryo extract ultrafiltrate (*75*). Our synthetic approach was to add defined components to the protein fraction of HS and/or the ultrafiltrate of chick embryo extract (*76*). These supplements included an amino acid mixture formulated from chromatographic analyses of the free and conjugated amino acids in the complex biologic medium (*69*, *70*); Earle's saline formed the diluent, and vitamins with certain other components from mixture 199 of Morgan et al. (*77*) were tested in groups (*78*). By 1954, fractionations, analyses of these fractions, and exploratory nutritional experiments made possible the formulation of a chemically defined medium, later designated NCTC-109; in January 1955 a line of NCTC clone 929L, designated NCTC 2071, was initiated in this serum-, protein-, and antibiotic-free medium, cultured continuously for 24 years thereafter (*79–81*), and found on subculture to proliferate reproducibly from a lower inoculum size than was possible with NCTC clone 929L in serum–embryo extract medium (*56*, *82*). This medium and the synthetic medium 858 of Healy et al. (*83*) were the first chemically defined media to support proliferation of an established mammalian cell line; these two media differ qualitatively and quantitatively in numerous components.

Some 30 additional cell lines from five species including man, monkey, hamster, rat, and mouse were adapted by gradual serum depletion to serum-free, chemically characterized medium NCTC-135 (differing from NCTC-109 in lacking cysteine) (*84–92*). The successful growth of cells in chemically defined medium could result from adaptation or from the selective multiplication of variants or mutants of the original cells. However, certain lines retained some functional differentiation and showed no more alterations than were observed in cells explanted from in vivo to serum-containing medium. In fact, analyses of numerous cell lines adapted to continuous growth in serum-free chemically defined medium showed, with few exceptions, enzyme profiles similar to those in serum-containing medium (*93*). Furthermore, normal embryo cells from mouse and rat tissues could be explanted directly to chemically defined medium and grown continuously thereafter in the absence of serum or exogenous protein (*94–96*).

Fischer (*97*) and Eagle (*98*) identified, in short-term studies, the essential amino acids, and Eagle (*99*) identified the essential vitamins for cell survival and proliferation. However, these essential components were always identified in a medium containing dialyzed serum which can prevent the development and manifestation of certain nutritional deficiencies (*100*). By use of serum-free, protein-free, chemically defined medium, we disclosed some additional requirements for long-term proliferation. Biotin was shown for the first time to be a requirement for continued proliferation (*101*); vitamin B_{12} and inositol were required by certain cell lines but were not required by others (*91*, *100–102*). An interrelationship between folic acid concentration, vitamin B_{12}, and nucleic acid synthesis in murine cells was established and analyzed (*103–107*). We showed for the first time that the nonessential amino acids are required for maintaining a high rate of cell proliferation in the absence of serum protein (*100*, *108*, *109*). Galactose could be substituted for glucose in cultures of mouse and human cells, but cell yield was reduced (*110*). In efforts to simplify and improve the growth-promoting properties of the medium, individual components and groups of components were evaluated by quantitative growth assays (*101*, *109*, *111–114*). Simpler media such as NCTC-126 and NCTC-163 were formulated, all components of which served some function or were necessary for cell survival, maximum proliferation, or prevention of cell fragility (*84*, *92*, *101*, *115*, *116*). Recently, the new NCTC formulation 168 was developed for human skin epithelial cells, a cell type of importance for carcinogenesis studies (*117*).

The successful growth of cells in serum-free, chemically defined medium can be attributed to several factors including the commercial availability of high-quality chemicals, instrumentation for obtaining pure water, and equipment and procedures to ensure chemically clean glassware (*55*). Earle developed, for the early carcinogen studies (*9*), a method and apparatus for the cleaning of glassware by digestion of organic residues with hot sulfuric–nitric acid in steam-jacketed Duriron kettles (*118*). He introduced, for heat sterilization, the use of Patapar wrapping paper, a vegetable parchment that minimizes the release of volatile toxic substances. Since house-generated steam usually contains toxic substances to prevent oxidation of pipes, Earle designed and had fabricated stainless-steel-clad autoclaves with self-contained indirect distilled water steam generators. No antibiotics were introduced into the cell cultures because they prevent ready detection of microbial contaminants that complicate interpretation of nutritional and biochemical data.

To facilitate culturing of cells in chemically defined media and to enhance usefulness of the cells, we examined commercially prepared powdered NCTC media and procedures for cryopreservation of cells. Critical evaluation of the ball-milled, powdered media with no added serum revealed deficiencies that limited their usefulness as serum-free media in certain nutritional and biochemical studies (*119*). Classical procedures for cryopreservation in liquid nitrogen were successfully adapted for cells grown in chemically defined medium (*120*). We were thus in a position to suspend life processes at any stage of culture and store the cells for later retrieval and study.

Not only have chemically defined media been useful for growing cells in stationary culture, but they are also useful for growing cells in agitated fluid suspension. However, a supplement of 0.12% methylcellulose (Dow type MC, 10–15 centipoises), a chemically characterized nutritionally inert polymer, was essential to prevent deterioration of cells by mechanical stresses imposed on them as a result of rapid fluid agitation (*121*, *122*). With this supplement, malignant cell lines, adapted to chemically defined medium, produced consistently high cell yields (*115*, *122*, *123*). Normal lines, such as LLC MK$_2$ derived from monkey kidney, failed to grow (*124*). The observations that methylcellulose substitutes for serum in agitated suspension culture and also promotes survival and proliferation of fragile cells grown in chemically defined medium in stationary culture (*125*) suggest that one role of the large serum protein molecules is to provide physical protection to cells during mechanical stress.

Analysis of the Role of Serum and Introduction of a Serum Substitute

Although we have shown that serum is not an absolute requirement for in vitro survival and proliferation, it facilitates initiation of cell lines and promotes cell proliferation. However, serum is not only a depot for bound nutrients such as trace elements, vitamins, and cofactors, but it is also a source of chemical variability and can introduce adventitious microbial contaminants such as mycoplasma as well as hormones, antibodies, enzymes, or cytotoxic factors (*126–128*). Diverse effects of serum on cells have been noted. For example, the addition of serum to chemically defined medium reversibly altered certain isozyme patterns of three lines of human epithelial-like cells (*129*). NCTC clone 929L cells, after their adaptation to a chemically defined medium, showed altered morphology, increased adhesion to glass substrate with reduced intercellular cohesion, and greatly decreased rates of cell migration (*130*) as revealed by time-lapse microcinematography (*131*). These changes could be reversed by addition of serum to the cultures (*130*). In addition, when added immediately after X-irradiation, serum modified the irradiation response of cultures by speeding their recovery (*132*). Addition of serum proteins to a chemically defined medium deficient in certain vitamins and amino acids prevented the development and manifestation of the nutritional deficiencies (*100*).

A low-molecular-weight (mol wt, <1,500), heat-stable growth factor from Bacto-peptone could substitute for serum and sustain continuous growth of a number of serum-dependent mammalian cell lines. Although the chemical nature of the biologically active component(s) is not yet firmly established, this factor is autoclavable and nonantigenic and may be of considerable value for vaccines and other biologics in obviating problems with viruses and other unknown components of serum (*133–135*). In addition, this factor shortens the time required for adaptation of cells from serum-supplemented medium to continuous growth in protein-free, chemically defined medium (*127*, *136*).

Identification of Serum Type, Visible Light, and Oxygen as Factors Influencing Chromosomal Stability and Cell Proliferation

The type of serum supplement was found to influence karyotypic stability. The chromosomes of mouse cells grown in HS-supplemented medium as compared with FBS-supplemented medium were more unstable, shifting rapidly from the diploid number and altering in morphology as a result of chromatid breaks and rearrangements (*137–142*). These observations suggest that HS produces chromatid breaks at a faster rate than FBS and/or FBS protects against chromatid breakage. In a recent study (*143*), the large molecule fraction of HS (excluded volume from Sephadex G-25) produced alterations in chromosome number and structure; also, HS caused chromatid breaks at or near the centromere as well as caused terminal chromatid exchanges resulting from breaks in the centromeric areas.

Another factor influencing karyotypic stability was found to be the oxygen concentration in the gas phase of the culture. Oxygen dissolved in the culture medium is essential for maintaining a normal respiration rate, but the Po$_2$ must not be damaging to the cell. The gas phase in most cell cultures is either residual air or an air:CO$_2$ mixture (18–20% O$_2$). Decreasing the oxygen concentration in mass culture from atmospheric (18%) to 1% decreased the number of chromosomal aberrations and the rate of shift from diploidy (*144–146*). In fact, 18% O$_2$ may be a factor in the evolution of heteroploidy and long-term cell lines (*147*, *148*). Lowering the oxygen concentration in the gas phase to 0–1% also enhanced survival and growth of single cells, whether malignant or normal, in a variety of culture media compared for their effectiveness in promoting clonal growth (*148*, *149*). The cytotoxicity or clonal growth inhibition produced by atmospheric oxygen could not be alleviated by addition of the reducing agents cysteine or thioglycollate (*150*). The oxygen sensitivity of freshly explanted mouse embryo cells or low-passage human diploid fibroblasts was greater than that of long-term heteroploid cell lines that had been continuously propagated at and adapted to the high oxygen level. Whereas a low oxygen level enhanced clonal growth, no difference in cell yield or glycolytic activity was observed between cultures at higher inoculum sizes as used routinely for mass culture that were gassed with 18% (atmospheric) O$_2$ (growth medium Po$_2$, ≈120 mm Hg) and those gassed with 1% O$_2$ (growth medium Po$_2$, ≈40–60 mm Hg). A Po$_2$ of 40–60 mm Hg is comparable to physiologic values of intercellular fluids in vivo. In mass culture, the respiratory activities of the many cells may adjust the growth medium Po$_2$ to the lower more physiologic concentration (*151*). In contrast to fibroblasts, epithelial cells in mass culture require the higher oxygen concentration for optimal growth (*152*).

Shielding cultures from room lights during routine handling also reduced the incidence of abnormal chromosomes including minutes and metacentrics that result from chromatid breaks and exchanges (*144*, *146*). Further studies showed that a single 3- to 20-hour exposure to low-intensity, cool-white fluorescent light (4.6 W/m^2) at 37°C produces chromatid breaks and exchanges in both mouse and human cells (*153*, *154*). The effective wavelength (405 nm) is in the visible range (*155*). The light-induced chromatid damage is enhanced by oxygen and can be almost completely prevented by the addition of catalase or glutathione with ascorbic acid to the culture medium during light exposure; superoxide dismutase has no effect (*153, 154*). These observations implicate H_2O_2 produced in the illuminated culture medium or in the cell as a causative agent. Light and oxygen in the presence of riboflavine, tyrosine, and L-tryptophan generate clastogenic (chromosome-breaking) amounts of H_2O_2 in the culture medium (*155, 156*). However, cells washed free of medium and illuminated in saline for 3 hours show chromosome damage to the same extent as cells illuminated in culture medium (*154, 155*). Furthermore, mannitol, a scavenger of $\cdot OH$ significantly decreases the light-induced damage (*154*). Thus both H_2O_2 and the derivative $\cdot OH$ generated within the cell during light exposure are agents that directly or indirectly cause the chromatid damage. Sodium selenite added to the cultures also significantly decreases the damage in a dose-related manner and may be necessary to maintain sufficient activity of glutathione peroxidase, a selenoenzyme that catalyzes the decomposition of H_2O_2 (*154*). Survival of cells in mass culture after exposure to visible light depends on the medium used and the cell type. Epithelial cells grown in medium NCTC-168 are more resistant to cytocidal effects of light than are fibroblasts (*157*). Light-induced cytocidal effects can be prevented by the use of tinted flasks (Taylor WG, Camalier RF: Unpublished observations).

Visible light in the presence of oxygen was found to have several other effects on cells in culture. Twenty-hour exposure at 37°C of mouse and human cells to low-intensity (4.6 W/m^2) fluorescent light produces DNA–protein cross-links. The effective wavelength(s) is in the visible region of the spectrum, 450–490 nm. The cross-linkage is medium mediated, proportional to the intensity of fluorescent light, enhanced by oxygen, decreased at high cell density, and insensitive to catalase. This linkage removed by digestion with *Tritirachium album* Limber proteinase K is between DNA and protein. These lesions are usually repaired within 24 hours. Light-induced cross-links were probably not discovered previously because the light was administered at high intensity under nonphysiologic conditions of low temperature and nutrient-deficient medium. Light causes more strand breaks than cross-links. Under nonphysiologic conditions, breaks predominate, whereas under physiologic conditions, breaks are repaired more rapidly than cross-links. Consequently, cross-links predominate, and this damage at the molecular level may lead to important biologic aberrations such as mutations, chromosome damage, and malignant transformation (*158, 159*).

Another effect of low-intensity light (6–9 W/m^2) was the enhancement of proliferation rate and life-span of human diploid fibroblasts. Whereas long exposure (>8 hr) of cells and medium to light produces toxic and/or growth-inhibitory photoproducts, especially for low-density cell populations, short exposures (3–4 hr) reproducibly enhance the proliferation rate in a reversible manner and significantly extend the life-span. This reversible response is mediated by a substance(s) generated by light exposure of culture medium (*160, 161*). Light produces some mitogenic substance(s) in certain components of the chemically defined medium (Parshad R, Sanford KK: Unpublished observations).

SPONTANEOUS MALIGNANT TRANSFORMATION IN CULTURE

Earle's primary research objective was to elucidate the mechanism of carcinogen-induced malignant transformation of mouse cells in culture. Even before his studies at NCI, he performed exploratory experiments to select a suitable tissue and carcinogen dose and to develop procedures for documenting morphologic changes (*162–165*). In assessing the neoplastic potential of tissue culture cells implanted in vivo, he observed that tumor cells exhibit more invasive, rapid growth and less necrosis at the intramuscular than at the subcutaneous site (*166*) and that carcinoma cells may initially give rise to tumors in vivo typical of the parent tumor but later, despite epithelial architecture, give rise to tumors simulating fibrosarcoma (*167, 168*). He documented a gradual morphologic alteration in carcinogen-treated cultures of mouse cells that resembled the morphology of cultured cells derived from a carcinogen-induced rat tumor (*169*).

Discovery of Spontaneous Neoplastic Transformation in Culture

In 1940 at NCI, Earle initiated a line of cells from normal subcutaneous connective tissue of a strain C3H mouse; when the morphology of the cells had stabilized, cultures were exposed to the carcinogen 20-methylcholanthrene, i.e., MCA, for periods ranging from 6 days to more than a year; untreated cultures were also maintained. Assays for malignant neoplastic transformation were made by im implantation of the cultured cells into C3H mice. Morphologic and growth changes associated with carcinogen dosage and similar to those reported earlier were observed (*9*). Furthermore, morphology was documented photographically with the unique cine- and still-microphotographic instrumentation he designed (*170, 171*). These morphologic alterations stabilized and persisted for years (*172–175*). Cells were first implanted in mice after 500 days in culture and 25 days after removal from the carcinogen (*176*). Sarcomas developed from the implanted cells irrespective of carcinogen dosage (*177*). One of the malignant cell lines, designated strain L and exposed for 111 days to MCA, was cultured continuously for 8 years, at which time a clonal population was derived, as noted earlier (*36*). The control untreated cultures also gave rise to tumors. This observation was interpreted as resulting from a possible contamination with the carcinogen, although alternative explanations were proposed (*176, 178*). The sarcomas originating from the cultured cells were shown to possess a metabolism characteristic of that of malignant tumors (*179*). The Golgi and mitochondria of the carcinogen-treated cells and derivative tumors showed few changes from those of untreated control cells (*180*).

With the passage of time, a progressive decrease occurred in vitro in the capacity of the mouse cell strains, including

NCTC clone 929L, to give rise to sarcomas when the cells were injected into animals of the inbred strain of origin (*181*), and the extent of vascular reaction elicited by each cell strain in transparent chambers in vivo varied with percentage of tumors produced (*182*). The decrease in tumorigenicity of NCTC clone 929L was subsequently shown to result from an immunologic incompatibility between the cells and mice of the inbred strain of origin (*183*). It is of interest that when NCTC clone 929L was later adapted to serum-free, protein-free, chemically defined medium, the cells gave rise to sarcomas in approximately 90% of animals inoculated. This marked increase in tumor-producing capacity could result from antigenic alterations or alterations in biosynthetic capacities that enhance transplantability of the cultured cells (*101, 184*). The results of these carcinogen experiments and those of Dr. George Gey, The Johns Hopkins Medical School, on rat fibroblasts (*185*) showed clearly that carcinogenesis can occur in vitro. However, it was still uncertain whether the neoplastic transformation of the mouse cells was induced or spontaneous.

In a subsequent study additional lines of mouse cells underwent neoplastic transformation in the absence of added carcinogen, and trace levels of MCA did not enhance the incidence. These results led to the conclusion that neoplastic transformation is a reproducible response of strain C3H mouse fibroblasts to the culture conditions used (*186*). Further studies showed that cell lines derived from a wide variety of normal tissues, including liver, kidney, epidermis, parotid gland, subcutaneous connective tissue, and skeletal muscle of different mouse and rat strains as well as cells from Syrian and Chinese hamsters, regularly undergo neoplastic transformation during long-term culture (*40, 94, 95, 137, 187–192*). Tumors arising from implants of the cultured cells were indistinguishable from many anaplastic sarcomas and carcinomas of in vivo origin. To date, two mammalian species, guinea pig and human, appear resistant to both spontaneous transformation in culture and foreign-body carcinogenesis (*193*).

Clonal Analysis of Neoplastic Transformation

With the development of a cloning procedure, two questions concerning neoplastic transformation in culture could be answered. 1) Is this a bona fide cell transformation or is it a selective process by which latent tumor cells in the tissue explant overgrow normal tissue components? 2) Would the change occur simultaneously or would it occur randomly in parallel cell lines grown from a single cell either in plasma clot matrix or with cellophane substrate but under otherwise similar culture conditions? A clone was developed from C3H mouse connective tissue. Parenthetically, the only relationship between this clone and clone NCTC 929L is that both were derived from C3H mice. During an 18-month study of 17 parallel lines of this clone, 8 failed to produce tumors in syngeneic hosts whereas 9 became tumorigenic. Clearly, from a single cell in culture, neoplastic cells arose by the process of transformation and not by selective overgrowth. The transformations appeared randomly, suggestive of mutational events (*187*). We continued two of the cell lines, one tumorigenic and the other nontumorigenic, for a comparative study of their properties in an effort to identify "markers" of neoplastic transformation. Nontumorigenic or nonneoplastic cells will be referred to henceforth in this paper as "normal." The normal line subsequently became transformed and gave rise to a low incidence of sarcomas. Markers of neoplastic transformation will be considered later.

Induction of Neoplastic Transformation by Viruses and Chemical Carcinogens

Because of the erratic nature of spontaneous neoplastic transformation in long-term culture, we attempted to induce a rapid and controlled transformation, preferably in a clonal population, before spontaneous transformation occurred. Our objective was to obtain paired normal and derivative neoplastic cell populations for comparative study. Two tumor viruses were examined as possible inducing agents, RSV and polyomavirus. The first step with RSV was to resolve the controversy concerning the specific tissue cell, monocyte or fibroblast, that becomes infected and transformed in vivo by RSV. Our studies showed that the fibroblast from subcutaneous connective tissue is the cell susceptible to infection. However, under our culture conditions, morphologic alterations were not induced. Furthermore, the lack of inbred chickens for assay of tumorigenicity and the rapidity with which the virus induces tumors in host tissues precluded adequate in vivo testing of the cultures (*194, 195*). Malignant transformations were produced repeatedly by polyomavirus in a clone of epithelial-like cells from C3H mouse parotid gland. However, soon after the virus-induced transformation, all control untreated cultures underwent spontaneous transformation (*40*). In Syrian hamster embryo cells, reputedly more stable than mouse cells in culture, malignant transformations could be induced by high-titered polyomavirus under certain conditions, but the transformations were not rapid nor entirely reproducible. In addition, hamster embryo cells did not exhibit a finite lifespan as previously postulated, and all hamster lines underwent spontaneous transformation (*190*). Although RSV continued replication in Rous sarcoma cells in culture, efforts to produce MuMTV at high titer in mouse mammary carcinoma cells were less successful. Cells were established in culture from spontaneous, primary, and transplanted C3H mouse mammary carcinomas known to contain MuMTV. Although the tumor cell lines continued to grow autonomously when implanted in vivo, MuMTV disappeared from the cells with prolonged culture. Continued virus replication in the cell was apparently not required for maintenance of the neoplastic state (*196*). Furthermore, high-titered and reproducible virus preparations could not be obtained from these cultures.

Chemical carcinogens, tested as inducing agents, produced malignant transformations in some Syrian hamster embryo cell lines, with the response neither rapid nor completely reproducible. Carcinogen treatment of mouse, rat, and Chinese hamster cell lines did not induce transformation nor enhance the spontaneous change as judged by tumorigenicity of the cells in syngeneic hosts (*192*). Cultures of human epithelial cells actively metabolized the environmentally ubiquitous carcinogen BP (*197*). At low noncytotoxic concentrations, BP formed adducts to cellular DNA. Because these adducts persisted for at least 7 days, they may accumulate with prolonged BP exposure. This finding suggests that chronic low-level exposure of human skin epithelium to BP may lead to an accumulation of DNA damage (*198*). For this reason, the culture of human skin epithelial cells under controlled conditions is important for in vitro carcinogenesis studies. However, human cells are less suitable for in vivo assays of tumorigenicity and have been less well characterized than cells from inbred rodents such as the mouse.

Because the induction of malignant transformation by tumor viruses or chemical carcinogens in rodent cells was not rapid nor always reproducible and was usually complicated by the almost simultaneous and/or erratic spontaneous transformation of control cultures, we continued our efforts to identify and control environmental factors that might influence or cause spontaneous transformations. One advantage of studying spontaneous in contrast to induced transformants is that responses to the exogenous inducing agents that are unrelated to malignant transformation are absent; thus properties uniquely associated with malignant transformation can be more readily identified.

Hypotheses Concerning the Etiology of Spontaneous Neoplastic Transformation

Intermittent anaerobiosis and cell crowding as causative factors.—Several hypotheses concerning the etiology of so-called spontaneous malignant transformation have been proposed through the years (*184*). Intermittent anaerobiosis was postulated as a condition that could induce malignant transformation. However, we observed no influence of anaerobic treatment on time or incidence of malignant conversion in two independent studies on lines of mouse cells (*199, 200*). Subsequently, certain observations suggested that the transformation in mouse cells is associated with activation of endogenous viruses of the murine leukemia–sarcoma complex; attempts to demonstrate such an incontrovertible association have been unsuccessful (*201–203*). An influence of high cell density on acquisition of neoplastic potential has also been reported. Some of our experimental observations prompted us to reassess this concept. Normal rat embryo cells maintained for approximately 3 years with regular medium renewals but with limited or no subculturing formed densely multilayered sheets in vitro but did not grow as sarcomas in vivo. In contrast, cells initiated from the same embryo cell suspension but maintained at a lower population density by repeated subculture became tumorigenic (*95*). In our reassessment of the postulate that high cell density with extensive cell–cell contact promotes malignant transformation whereas low cell density with limited cell–cell contact prevents transformation, we found that manipulation of inoculum size to maximize or minimize cell contact did not reproducibly influence malignant transformation. We concluded that serial culture of cells at low population density with limited cell–cell contact was insufficient to prevent transformation and that deliberate selection of colonies or cultures of well-spread, cytologically normal cells was necessary to maintain a normal cell population. Contrariwise, serial culture of cells at high density conferred a growth advantage to malignant cells which, in contrast to normal cells, are usually less anchorage-dependent and thus capable in crowded culture of proliferation in multilayers (*204*).

The aberrant methylation hypothesis of malignant transformation.—The observation that certain tumor tissue extracts have a greater methylating capacity than do extracts of normal tissue cells led to the concept that altered nucleic acid methylation may be the initiating or necessary chemical event in at least some types of malignant transformation (*205*). This hypothesis was evaluated in a more rigidly controlled biologic system than that used previously. Mouse cells transformed spontaneously in culture in the absence of exogenous virus or chemical carcinogen and the normal cells from which they arose were compared under the same culture conditions and after the same period in vitro; both cell populations also grew at the same rate in culture. The malignant cell extracts had a greater methylating capacity than did extracts of the normal cells (*206, 207*). A consistent but small difference between tRNA methylation was also observed in the paired lines (*208*). These results are consistent with the aberrant methylation hypothesis. No difference was observed between the paired cell lines in methylation of satellite DNA; both heavy- and light-strand DNA had essentially equal amounts of 5-methylcytosine despite a 1.5-fold higher cytosine content in the heavy strand (*209*). The biologic function of methylcytosine in mammalian cell DNA is still unclear. Although methylcytosine was known to be present in nuclear and mitochondrial DNA, it was shown for the first time to occur also in rat liver microsomal DNA, which has distinctly different properties from those of mitochondrial and nuclear DNA (*210*). A qualitative difference was observed between the methylase activities of normal and malignant mouse mammary tissue, but the normal lactating tissue extracts had a greater capacity to methylate RNA than did the tumor tissue extracts (*211*). These conclusions are consistent with the aberrant methylation hypothesis, with the reservation that aberrant does not imply hypermethylation.

In these studies, support for the methylation hypothesis was provided by the discovery of methyltransferases in all RNA tumor viruses examined. These viruses included AMV (*212*), RSV (*213*), RAV-1 (*213*), MuMTV (*211*), and, in addition, intracisternal A-particles which have several biochemical properties of RNA tumor viruses (*214*). These A-particles, found consistently in tumors and embryo cells but not in adult tissues, are frequently associated with C-type particles; however, they are neither infective nor apparent precursors of immature forms of C-particles (*215*). The column chromatographic procedure developed for methylase assay facilitates identification, purification, and characterization of these enzymes (*216*). An N^2-guanine methyltransferase was partially purified from chick embryo cells (*217*), purified 120-fold from AMV, and characterized (*218*). Six methylases, indistinguishable from cellular enzymes and not found in other RNA tumor viruses, were associated with the intracisternal A-particles; five were found in the nucleoprotein core, possibly having been packaged in the core during viral synthesis (*214*). N^2-guanine RNA methyltransferase was integrally associated with both

MuMTV and its putative nucleoprotein core, the intracytoplasmic A-particle (*211*). In AMV, the methylase is not a core component, is possibly of cellular origin, and may have a function in the virus life cycle (*219, 220*). N^2-guanine RNA methyltransferase is also associated with RSV and RAV-1, and an additional purine methylase N^1-adenine RNA methyltransferase was found in RSV but not in AMV or RAV-1. Although all examined RNA tumor viruses alter methylation of nucleic acids, it is still uncertain whether these methylations are primary or causal, secondary, or concomitant to malignant transformation (*221*).

Elimination of Suspect Causative Agents in Malignant Transformation

Our primary objective in developing a chemically characterized culture medium was to determine whether cells grown in this better defined environment still undergo malignant transformation. Five lines of C3H mouse cells (*96, 222*) and three lines of rat embryo cells (*95*) were initiated and maintained continuously in serum- and protein-free, chemically defined medium; all mouse lines transformed after prolonged culture, but the rat cells remained normal for years. In four of the mouse lines, cells in primary culture grew as sarcomas even before they could be subcultured. Also, normal mouse tissue cells underwent malignant transformation when explanted into Millipore diffusion chambers inserted ip into C3H mice and maintained in the same chamber without the mitotic stimulation associated with subculturing (*223*). The transformed mouse lines with one exception were found to be free of known murine viruses (*96, 222*). The experiments with mouse cells in chemically defined medium ruled out exogenous viruses, known chemical carcinogens, and hormones as the causative agents of these transformations. The results also supported the concept of spontaneous change.

Influence of Type of Serum on Malignant Transformation

The first evidence that these transformations were not strictly spontaneous but could be induced or influenced by environmental factors was the discovery that the type of serum added to the medium accelerated and increased the frequency of malignant transformation. C3H mouse cells cultured in chemically defined medium supplemented with gelding HS became transformed after short culture periods ranging from 3 to 6 months, whereas cells cultured with FBS became transformed after more variable and considerably longer periods extending to more than 2 years (*224*). These observations were, in general, confirmed in a number of studies and also were verified in cells from other mouse strains (*94, 137, 138, 189, 222*). Of types of serum tested, including fetal horse, stallion, mare, early fetal bovine, bovine calf, and adult bovine, the most active in promoting transformation were stallion, gelding horse, and bovine calf; however, FBS reproducibly delayed or inhibited transformation (*139, 140, 225*). Cells exposed to HS for as little as 15 days became transformed even when subsequently grown in FBS; in fact, the longer the culture was exposed to HS before it was transferred to FBS, the shorter was the time required for its transformation (*226*). Thus some carcinogenic factor(s) in HS appears to initiate malignant transformation. This factor(s) is apparently heat-stable (*126*). FBS added to culture medium supplemented with HS or bovine calf serum delayed or prevented the malignant transformation that occurred in the absence of FBS (*226, 227*). Therefore, some influence in FBS appears to protect against such transformation. Efforts to identify and characterize the active factors in HS and FBS were unsuccessful in that none of the isolated serum fractions or combinations of fractions reproducibly controlled the malignant transformation (*139, 143, 203, 228*). However, as noted earlier, the type of serum that increased the frequency of transformation also caused karyotypic instability. Conceivably, an environmental factor that produces karyotypic instability of cultured cells may also induce carcinogenesis in vitro. In support of this concept, we note that the more stable the karyotype, the less frequent the occurrence of malignant transformation among cells from different species (*229, 230*). The two other environmental factors producing karyotypic instability, atmospheric oxygen and visible light, were examined as possible causative agents.

Light and Oxygen as Causative Agents in Malignant Transformation of Mouse Cells

Repeated exposure of mouse cells to visible light and atmospheric oxygen was found to enhance or induce malignant transformation. Cell lines initiated from different pools of C3H mouse embryos were divided into sublines maintained either shielded from light or repeatedly exposed to low-intensity light (4.6 W/m^2); cultures were gassed with either atmospheric (18%) or 0–1% O_2. Five of seven lines became tumorigenic during the test period. In two of these lines, tumors developed only from the light-exposed cells; in another, the transformation occurred earlier in the light-exposed cells, and in the remaining two, tumor latent periods in syngeneic hosts were significantly shorter in the cultures exposed to light or gassed with atmospheric oxygen (*144*). The so-called spontaneous transformations of mouse cells even in serum-free, chemically defined medium (*96, 222*) were apparently produced by the repeated exposure of cells to room lights and by continuous exposure to a high concentration of oxygen in the culture medium.

When we analyzed the chromosomes of tumors arising from implanted tissue culture cells, we observed a wide and characteristic distribution of chromosome numbers and types similar to that observed in the precursor culture cells; this observation indicated that most of the karyotypically diverse cells in culture were malignant and capable of continued progressive growth in vivo (*231*). Neither could a common pattern of chromosomal constitution characterize the tumors, nor could any specific chromosomal aberration be correlated with the onset of malignant transformation of mouse cells in vitro, although the incidence of abnormal chromosomes tended to increase at about the time of malignant transformation (*139, 141, 222, 232*). Chromosomes of rat cells were more stable, but some alterations occurred long before malignant transformation; no chromosomal alteration or pattern of chromosomal change characterized the malignant as compared with the normal rat cell populations (*95*). Nevertheless, the apparent association between karyotypic instability and accelerated malignant transformation induced by serum, visible light, and atmospheric oxygen suggests that agents in culture that damage chromosomal DNA may also initiate carcinogenesis (*144*).

Enhanced Susceptibility to Chromosome Damage in Relation to Malignant Transformation

As mentioned earlier, repeated exposure to visible light in the presence of atmospheric oxygen causes chromosomal aberrations and also enhances malignant transformation of mouse cells in culture (*144*). However, some cell lines developed chromosomal aberrations and transformed even when shielded from light and cultured at a low oxygen concentration. These observations suggest that additional factors, extrinsic and/or intrinsic, operate in malignant transformation. Extrinsic factors may include other as yet unidentified chemical agents in the culture environment or fluctuations in the oxygen concentration of the medium. Although cultures were gassed with 0-1% O_2, the cells received unavoidable brief exposures to atmospheric oxygen during culture manipulations. One intrinsic factor is the increased susceptibility of malignant mouse cells to light-induced chromatid damage, which was determined experimentally by the enumeration of chromatid breaks and exchanges after a single 20-hour exposure to low-intensity (4.6 W/m^2) fluorescent light. The frequency of light-induced chromatid breaks and exchanges was significantly higher in the malignant cells than in their normal precursors, and this increase was associated with their spontaneous neoplastic transformation (*233*).

In contrast to mouse cells, human cells from normal donors do not develop the increased susceptibility to light-induced chromatid breaks during culture. Human cells are also transformed with difficulty by carcinogenic agents, maintain a stable karyotype, and have not with one possible exception (*234*) been reported to undergo spontaneous transformation in culture. After a period of culture, however, human tumor cells, human cells transformed in culture by chemical carcinogens to malignant cells, and cells from donors genetically predisposed to a high risk of cancer (xeroderma pigmentosum and ataxia telangiectasia) show an increase in susceptibility as compared with the susceptibility among their normal counterparts or cells from normal donors [(*235*); Parshad R, Sanford KK, Jones GM: Unpublished observations]. Thus malignant transformation in human cells, as in mouse cells, is apparently associated with an increased susceptibility to light-induced chromosomal DNA damage. This increased susceptibility as discussed later results from deficiencies in the repair of DNA damage; in fact, the loss of DNA repair capacity may be an essential step in the progression to malignant neoplastic state.

MARKERS OF NEOPLASTIC TRANSFORMATION IN CULTURE

A major objective of this laboratory was the establishment of differences at the cellular and molecular level between the normal cell in culture and its malignant derivative. Cellular changes rigidly associated with malignant transformation could provide in vitro criteria of transformation and be useful in designing strategies for cancer treatment. Three approaches to meet this objective were used. In the first, a clonal population of fibroblasts from adult mouse connective tissue was observed during neoplastic transformation and was examined for morphologic and physiologic alterations. In the second approach, a transformation system was developed with a well-characterized, metabolically active, highly differentiated cell type, e.g., the liver parenchymal cell, and any alterations in differentiated properties associated with transformation were elucidated. In the third approach, normal and neoplastic cell pairs of common origin, some from the same cell, were compared; such pairs were frequently taken from frozen stocks that had been cryopreserved at various stages of in vitro life. In these studies, cells from inbred animals were used primarily to facilitate the in vivo assay for malignant transformation.

The In Vivo Assay for Malignant Transformation

The distinguishing feature of malignant neoplastic cells is their capacity for uncontrolled invasive growth leading to destruction of normal tissues, sometimes metastasis formation, and ultimate death of the affected animal. In view of this definition, our conclusive test for malignant transformation of cells in culture was the demonstration of their capacity to grow as malignant neoplasms when implanted into compatible hosts. The implantation of cells in vivo presents certain difficulties, particularly those related to histoincompatibility, a result of antigenic changes in the cultured cells or of genetic drift in the recipient animals. Therefore, implants are commonly made in X-irradiated or immunosuppressed animals (*183*), the nude mouse, or immunologically privileged sites such as the anterior chamber of the mouse eye (*94*) and the hamster cheek pouch. The in vivo assay not only is time consuming but also requires large numbers of cells. Furthermore, results are difficult to interpret, especially if they are negative. Therefore, reliable criteria of malignancy are needed that correlate with tumorigenicity in vivo and that directly apply to cells in culture. Such criteria might also provide insight into the progression of cellular and molecular events in malignant transformation.

Clonal Analysis of Cellular Changes in Malignant Transformation

The cells of the first carcinogenesis experiments were heterogeneous populations of fibroblasts from connective tissue. With the introduction of cloning, a better controlled cell system was obtained inasmuch as normal and neoplastic cells were both derived in culture from the same cell. However, as noted earlier, the normal cells ultimately became transformed and produced a low incidence of sarcoma. Cells of the "high" and "low" tumorigenic lines were found to be antigenic to mice of the inbred strain of origin and to cross-react with each other and also with the unrelated NCTC clone 929L cells (*44, 236*). Apparently, these two unrelated clones of C3H mouse cells, NCTC clone 929L and both lines of the second clone, had acquired the same new transplantation antigen(s) after their neoplastic transformation in culture. Although both high and low lines had become antigenic to the C3H mouse and both proliferated at the same rate in vitro, their proliferation rates in vivo differed widely. The difference in tumor production by the two lines resulted from the more rapid proliferation in vivo of the high tumorigenic line to establish a critical tumor mass before host immunity developed (*236*).

A clonal analysis of each line showed that cells of the low tumorigenic line differed from those of the high tumorigenic line in heritable characteristics including a lower rate of glycolysis, lower activities of the enzymes metabolizing glucose oxidatively, longer tumor latency in vivo, and reduced capacity to induce a vascular response in the host (*44, 86, 237–240*). The type of culture medium in which the cells had been grown influenced their transplantability and tumorigenic potential in syngeneic hosts (*44*). Growth of the low-line cells in mice for one generation significantly increased their tumorigenic potential, and this increase was shown to result from an enhanced resistance to the immunity induced by the cells (*241*). Hereditary alterations in enzyme activities and morphology were demonstrated within a clone derived from one of the high-line tumors (*46, 242, 243*). All these lines and clones showed marked karyotypic alterations (*244*). This genetic instability can account for the morphologic and biochemical alterations and the acquisition of neoplastic potential observed in these cells during continuous culture.

Characterization of Differentiated Cells in Continuous Culture

The large-scale suspension and surface-substrate cultures produced adequate masses of cells for analyses of biochemical properties. Our objectives were to identify cells in culture as to type and tissue of origin, to determine whether they maintained differentiated function and structure, and to establish any effects of medium or growth conditions on biochemical behavior. A cell line of particular interest for characterization was derived in 1948 from the liver of a 2-day-old C3H mouse (*42, 245*). In contrast to 10 murine fibroblast lines that were negative for glycogen, this line and a derivative clone stored glycogen even after 12 years in culture (*246–248*). After prolonged culture in vitro and an extended latent period in vivo, the clonal derivative produced tumors resembling anaplastic carcinomas of hepatic origin (*188*). The cells could then be grown in agitated fluid suspension for such characterizations as growth kinetics, glycolysis, glutamine effects on metabolism, and yields of α-keto and certain amino acids in the depleted medium (*249–251*). The liver cells, after years of culture and malignant transformation, maintained certain differentiated properties of the tissue of origin. These properties included a high arginase activity, which was considerably higher than that observed in six lines of mouse fibroblasts of connective tissue origin or in HeLa and was about 75% of that in mouse liver, high rhodanese (thiosulfate sulfurtransferase) activity, and detectable activity of four steroid reductases characteristic of liver parenchymal cells (*46, 84, 248, 252*). β-D-Glucuronidase activity was greater in the cultured cells than in the intact liver (*253*). The cells were deficient, however, in activities of catalase and uricase (urate oxidase) (*254*). Certain enzyme activities such as catalase and alkaline phosphatase declined during culture of all cell lines examined, regardless of the tissue of origin, whereas high acid phosphatase was maintained during serial culture of cells of adult, neonatal, or embryonic origin (*93, 138*).

Four additional studies indicated that structural or functional differentiation can be maintained during prolonged culture of other cell types. In the first study, well-differentiated murine mammary carcinoma maintained differentiated architecture and the characteristic high arginase activity after 1.5 years and 35 transplant generations in vitro (*45*). However, other murine neoplasms including mammary carcinoma, hepatoma, melanoma, and thyroid carcinoma, when continuously cultured in vitro, produced tumors in vivo resembling sarcoma (*45, 167, 168, 255*). In vivo transplantation of mammary and pulmonary carcinomas has also led to "sarcomatous" change. Either malignant epithelial cells during prolonged culture lose their differentiated morphology, or the stromal tissue of the original tumor undergoes malignant transformation in vitro. Our experiments provided evidence for both concepts. A clonal analysis showed that cell lines from certain mammary carcinomas can assume fibroblast-like morphology in vitro and lose arginase activity, but they retain in vivo properties of anaplastic carcinoma, i.e., cyst formation. Also, by growing tumor transplants in a hybrid host to replace the original stroma with hybrid cells, we showed that stromal tissue in culture can undergo malignant transformation (*45*). In a second study, cultures of human hydatid mole continued to secrete gonadotropic hormone in large amounts for periods exceeding 1 year (*30*); in a third study, cells of a murine melanoma continued to produce melanin for more than a year while rapidly proliferating in culture (*255*). Finally, in the fourth study, C3H mouse fibroblasts, human epithelial cells, and monkey kidney cells, as expected, remained immunologically species-specific after years of proliferation in culture (*115*). However, many cell lines after prolonged culture lose certain differentiated properties of the tissue of origin (*93, 248*). Although this loss of differentiated properties may be associated with random mutation, induced changes in DNA, or quantitative changes in enzyme activities, it has not been rigidly correlated with the onset of malignant transformation.

Comparison of Paired Normal and Malignant Cell Populations

In this approach to determine markers of neoplastic transformation, we looked for differences between populations of normal cells and their malignant dervatives. For this purpose we developed cell lines, normal and spontaneously transformed tumorigenic, both from a common cell pool or even from the same cell to minimize differences in tissue or cell type. Cell populations cryopreserved before and after spontaneous malignant transformation also served as paired cell lines.

We found that several properties postulated as markers of malignant transformation cannot be applied with confidence to all cell systems because the markers were not reliable when tested on these more biologically controlled paired cells. These properties include agglutinability by certain plant lectins (*256*), loss of contact inhibition or density-dependent inhibition of growth with "piling-up" of cells (*184, 257, 258*), acquisition of infinite growth potential (*257*), capacity to grow in low serum concentration (*259*), exaggerated incidence of surface microvilli, blebs, and ruffles (*260*), disorganized or decreased numbers of microtubules (*261*), production of plasminogen activator (*262*), thickening of ruthenium red-staining coat (*263*), and resistance to the cytotoxic effect of 7,12-dimethylbenz[*a*]anthracene (*264*). Multilayering or piling-up of cells may be more influenced by cell type, culture density, age of culture, type of culture medium, and frequency of medium renewal than by the malignant or normal state of the cells. For example, carcinoma cells can show monolayer growth, whereas normal embryo cells can grow in multilayers (*33, 138, 184, 230, 232, 257, 258, 265*). An enhanced growth rate and saturation density are observed in malignant as compared with normal cells under certain conditions in short-term culture. However, similar growth properties can develop in long-term normal cell lines. Therefore, these criteria are not applicable to all cell systems (*259, 265, 266*). Although we observed no conspicuous increase in aerobic glycolysis with malignant transformation, an enhanced anaerobic glycolysis was usually observed in both virus-induced and spontaneously transformed malignant cells as compared with their nontumorigenic counterparts (*86, 138, 204, 265, 267*). We also found that fetal antigens can be re-expressed in adult cells during culture and may be associated with their spontaneous malignant transformation (*268*).

Criteria for Identification of Malignant Cells in Culture

Cytology and colony morphology.—Cytologic criteria of cancer as applied to tissue or exfoliated cells in vivo prompted us to examine the cytology and colony morphology of the paired cell lines as well as to follow changes occurring during malignant transformation of mouse, rat, and hamster cells in culture. Certain changes that were detected more readily with the light microscope than with the electron microscope (*269*) correlated with the onset of tumorigenicity or neoplastic potential and provided criteria for identification of malignant cells in culture, applicable to spontaneous, virus-induced, and chemically induced transformations of fibroblasts or epithelial cells (*262*). These criteria included increased cytoplasmic basophilia, reduced spreading of cytoplasm on a solid surface substrate, random orientation, increased separation of cells, cell underlap or crisscross growth, heterogeneity in cell size and shape, nuclear abnormalities, increased nuclear:cytoplasmic ratio, increased nucleolar size and number, and tendency of cells to form cords or clumps. Criteria were applied to two types of stained preparations: 24- to 48-hour outgrowths of cells migrating from small clumps inoculated on cover glasses and colonies arising from proliferation of trypsinized single cell suspensions plated in plastic flasks (*270, 271*). Although no single morphologic feature could always be associated with malignant transformation, combinations of features showed a high correlation with tumorigenicity. Cytologic diagnoses were consistent with results of in vivo assays in 92% of the numerous cultures examined (*138, 143, 191, 192, 204, 225, 257, 259, 265, 272–274*). The reproducibility of the changes, even within populations derived from one cell in culture, and their regular association with malignant transformation suggest that morphologic changes are direct manifestations of the malignant transformation.

Reduced cytoplasmic spreading, measurable as a decrease in mean projected area of attached cells, was successfully used to assay the transition of rodent cells from normal to tumorigenic (*275*). A comparison of seven pairs of malignant and normal cell lines examined under identical culture conditions provided quantitative evidence that a decrease in projected area of cell and nucleus and a decrease in dry mass of lamellar cytoplasm (the thin peripheral cytoplasm of cells adherent to solid substrate) characterize the malignant cell (*276*). With reduced cytoplasmic spreading, the surface:volume ratio of the cell also decreases, and this decrease may affect exchange of nutrients and metabolites (*230*). This reduced spreading could result from deficiencies in elaboration of plasma membrane with associated lamellar cytoplasm or from cytoskeletal alterations.

The reduction in surface area of malignant cells might be illusory especially if residual cytoplasm and cell membrane were stored in the form of microvilli or other cell surface projections not visible by the light microscope (*259, 275*). In fact, an exaggerated incidence of microvilli and other cell surface projections has been reported as characteristic of tumor cells. For the comparison of the topography of populations of asynchronously dividing normal and malignant cells unperturbed by disruptive synchronization methods, it was first necessary to establish whether the paired normal and malignant cells undergo predictable changes in surface morphology as they progress through the cell cycle. No influence of cell cycle on surface topography was observed. Furthermore, our scanning electron microscopy studies revealed no increased incidence of cell surface projections including microvilli, blebs, and ruffles on the malignant cells as compared with their normal counterparts, both derived in culture from the same cell (*260, 277, 278*). These findings support the concept that the malignant cell as compared with its normal precursor has a decreased surface area relative to mass resulting from a decreased elaboration of plasma membrane and associated lamellar cytoplasm.

The reduced cytoplasmic spreading and rounding of transformed cells leading to an apparent increase in nuclear:cytoplasmic ratio and basophilia could also result from alterations in distribution or amount of cytoskeletal components including microtubules and microfilament bundles (stress fibers or actin cables). An examination of normal and malignant cells of the paired lines by polarizing microscopy of living cells and by indirect immunofluorescence microscopy of the fixed cells treated with antibody against tubulin (microtubule protein) or actin revealed no disorganization or decrease in numbers of microtubules in the malignant cells. However, when these cells were compared with their normal counterparts, the malignant cells appeared to have thinner and fewer actin cables when examined by both polarizing and indirect immunofluorescence microscopy (*261*).

Another criterion of malignant transformation, in addition to decreased cytoplasmic spreading, is the loss of parallel orientation of cells. The orientation of cells is determined by their direction of locomotion, which was analyzed by microcinematography of paired normal and malignant cells derived in culture from the same cell and filmed under identical culture conditions. Individual normal cells during sequential 2.5-hour periods tended to maintain the same direction of locomotion, whereas the malignant cells had a random pattern of locomotion; the malignant cells also showed a higher rate of locomotion. This random pattern and loss of parallel orientation may result from the decreased amount of lamellar cytoplasm (consequently fewer attachment sites to substrate), fewer actin cables, and higher migration rate (*279*).

Loss of anchorage dependence.—Malignant cells frequently show a progression of morphologic changes from decreased cytoplasmic spreading on surface substrate to rounding, ultimate detachment, and growth in suspension. This loss of substrate or anchorage dependence has been measured by the capacity of cells to divide and form colonies in a semisolid matrix such as agar (*280*), agarose, or methylcellulose. This assay was used successfully to discriminate between paired normal and malignant rodent cell lines of fibroblast origin; growth in agarose correlated with tumorigenicity in vivo (*273*).

Growth in agarose as a selective assay for malignant cells emphasizes the importance of loss of anchorage dependence for growth of cells as cancer in vivo (*273*). In the in vivo assay, if suspensions of trypsinized cells are injected, those cells that are anchorage-dependent may not have adequate or suitable substrate on which to attach and grow. Boone (*281*) presented some evidence that substrate-dependent, presumably normal cells implanted in vivo attached to a solid substrate (polycarbonate plates or glass beads) continue to grow and produce tumors. Tests of this concept with paired normal and malignant cell lines showed that some cells, nontumorigenic when implanted in suspension, were tumorigenic when implanted attached to polycarbonate plates or glass helices. The transplantability of malignant cells implanted on solid substrate was also enhanced. The plate implant test proved to be one of the most sensitive bioassays for the malignancy of cultured cells (*282*).

Reduced anchorage dependence rather than loss of "contact-inhibition of mitosis" probably accounts for the changed growth pattern observed in certain malignant transformations in culture. Cessation of growth in confluent monolayers of normal cells is usually interpreted as the result of contact inhibition of mitosis. An alternative interpretation is that cell crowding inhibits division of anchorage-dependent normal cells by limiting the area of solid substrate available for cell attachment, spreading, and mitotic division. Because malignant cells are less anchorage- or substrate-dependent, they can continue proliferating under conditions of limited or unavailable solid substrate (*138, 230, 257, 258*).

Susceptibility to killing by activated macrophages.—Numerous studies have shown that activated mouse peritoneal macrophages selectively kill tumor cells in vitro in a reaction that requires close apposition or direct contact between the target cell and the macrophage. We found that the macrophage reaction also discriminates between normal and malignant cells of paired lines derived in vitro from the same cell or cell pool (*204, 283*). The reaction can be visualized in a confluent layer of target cells as a clearing or plaque overlying a small area of attached macrophages (*284*) and can be quantified as released label from tritiated thymidine-prelabeled target cells (*285*). The dynamics of both the macrophage reaction and the cytotoxic T-lymphocyte reaction with tumor cells were analyzed by microcinematography. The translational movement of activated macrophages on a layer of tumor cells was up to five times the rate observed on normal cells. The macrophage–tumor cell interaction was characterized by repeated, relatively short contacts, inducing cytostasis or killing of the tumor cell, but similar repeated contacts with normal cells did not lead to cell destruction (*286*). The capacity of a single immune cytotoxic T-lymphocyte to lyse more than one allogeneic target cell was also clearly demonstrated (*287*). The mechanism to account for the specific killing of tumor cells by activated macrophages is still unknown. Some evidence supports the concept that H_2O_2 formed and released by the macrophage on contact is the mediator of this cytotoxicity (*288*).

The increased sensitivity of malignant cells to chromatid damage by H_2O_2 and its derivative ·OH could result from loss or inactivation of cellular defense enzymes such as catalase or glutathione peroxidase that destroy H_2O_2. However, these enzyme activities were similar in paired normal and malignant cell populations (*235, 289*). Another possibility is that the susceptible cells have an impaired capacity to repair the DNA damage produced by H_2O_2 and its derivative ·OH.

Deficiency in DNA Repair Capacity

As noted earlier, mouse cells spontaneously transformed in culture, human tumor cells (Parshad R, Sanford KK, Jones GM: Unpublished observations), and human cells transformed in culture by chemical carcinogens show an increased incidence of chromatid breaks after exposure to fluorescent light when these cells are compared with their normal counterparts (*233, 235*). Chromatid breaks represent unrepaired DNA double-strand breaks, and their increased incidence reflects an impaired DNA repair capacity. The extent of DNA repair is also influenced by the stage of the cell cycle at the time of exposure to the damaging agent [(*289*); Parshad R, Sanford KK, Jones GM, Tarone RE: Manuscript in preparation]. Malignant mouse and human cells were susceptible to chromatid breaks when these cells were exposed to light during late S–G_2, whereas their normal counterparts were not. Addition of a known inhibitor of DNA repair, caffeine, during late S–G_2 light exposure had no effect on the frequency of chromatid breaks in the malignant cells, but caffeine significantly increased chromatid breakage in the normal cells. These results suggest that normal mouse and human cells have a caffeine-sensitive mechanism(s) for repair of DNA strand breaks resulting from light exposure during late S–G_2, whereas this mechanism(s) is absent or deficient in the malignant cells.

In additional experiments, mouse and human cells were exposed to light during G_1 and subsequently treated with caffeine. The cytogenetic findings are consistent with the concept that the malignant mouse cells, which are normally less efficient in excision repair than human cells, are also deficient in replication repair; in contrast, when compared with their normal counterparts, the malignant human cells are deficient in excision repair of G_1 light-induced DNA damage [(*289*); Parshad R, Sanford KK, Jones GM, Tarone RE: Manuscript in preparation]. However, the deficiency in the human cells is compensated by effective replication repair during the subsequent S-period. Thus two basic defects in malignant mouse and human cells were disclosed by the analysis of responses to damage inflicted at different stages of the cell cycle.

Since light-induced damage is mediated through the intracellular generation of H_2O_2 and its derivative ·OH (*153, 154*), both of which are produced during X-irradiation, we also compared the incidence of chromatid breaks following X-irradiation during G_2 in the line of normal human fibroblasts KD and its malignant derivative HUT-14 (Parshad R, Gantt R, Sanford KK, Jones GM, Tarone RE: Submitted for publication). In this unique study, the extent of chromatid damage was quantitatively determined after X-radiation was applied exclusively in the G_2 period of the cell cycle or within 1.5 hours of metaphase. The malignant cells showed significantly more chromatid breaks and gaps than their normal counterparts. Exposure of cells to inhibitors of DNA repair, caffeine and Ara-C, immediately after their irradiation significantly increased the X-ray-induced chromatid damage in the normal cells but had little influence on the malignant cells. These results suggest that the DNA damage induced by X-ray during G_2 in the normal KD cells is repaired to a large extent by a mechanism(s) sensitive to both caffeine and Ara-C, whereas the malignant derivatives are totally defective in this mechanism(s). In additional studies (Parshad R, Sanford KK, Jones GM: Unpublished observations), all human tumor cell lines examined showed a defect in repair of X-irradiation-induced chromosomal DNA damage inflicted during the G_2 period of the cell cycle. No such defect was observed in a comparable number of fibroblast lines from normal, healthy donors. These findings with X-irradiation confirm and extend our previous observations of deficiencies in malignant cells of both mouse and human origin in the repair of light-induced chromosomal DNA damage inflicted during late S–G_2.

A MECHANISM OF SPONTANEOUS MALIGNANT TRANSFORMATION IN CULTURE

From our experimental findings, we conclude that the so-called spontaneous malignant transformation of mouse cells in culture is not spontaneous but is induced by specifically identifiable environmental factors. These factors include a chemical component(s) in serum, visible light, and high concentration of oxygen. These factors also cause chromosomal DNA damage. The light-induced chromosomal damage results from unrepaired DNA double-strand breaks produced directly or indirectly. We found that, as compared with normal cultures or cells from normal human donors, mouse and human cells following their malignant transformation in culture and human tumor cells have lost their capacity to repair this type of DNA damage. These findings support the concept that DNA damage and deficient DNA repair are implicated in the process of malignant transformation. Possibly unrepaired DNA damage at specific gene loci leads to the activation of cellular genes for transformation.

The light-induced DNA damage results from the intracellular generation of H_2O_2 and the derivative ·OH. Under physiologic conditions, these products are normal metabolites whose levels are regulated in vivo by defense enzymes and by the vascular control of oxygen supply to the tissues. However, these products are potentially dangerous (*290*), and it has been suggested that spontaneous human cancer may arise from DNA damage caused by their excessive endogenous production (*291*). We postulate that mouse cells that have an exceedingly low catalase activity are particularly susceptible to malignant transformation in culture because they are repeatedly exposed to visible light, continuously subjected to nonphysiologic high concentrations of oxygen in the culture medium, and eventually acquire a deficiency in repair of the DNA damage produced by these environmental agents.

Cancer Incidence in Humans: Relationship to Plasma Lipids and Relative Weight[1,2,3]

R. B. Wallace,[4] C. Rost,[4] L. F. Burmeister,[4] *and* P. R. Pomrehn[4]

ABSTRACT—Surveillance was done on cancers in subjects in rural Iowa for 6 years after they participated in a cardiovascular risk factor-screening program. Among 5,565 men and women 20-94 years old at screening, 131 persons were identified as having cancers. Each cancer patient was matched to a control without cancer, and differences in antecedent plasma cholesterol and triglyceride levels and relative weight were sought. Mean relative weight at screening was lower among cancer patients of both sexes than among controls. Plasma cholesterol levels were lower among male patients and higher among female patients than among controls, with the differences more prominent for those less than 60 years old at screening. In males, the lower cholesterol levels occurred only in those with neoplasms developing within 24 months of screening. The higher cholesterol levels among female patients with cancers limited to gonadal hormone-related sites were not time-dependent. Triglyceride levels were not significantly different between cancer patients and controls in any analytic group, but triglyceride levels did closely parallel cholesterol alterations. A minimum of 1% of the cohort had diagnosed cancers before the screening program.—JNCI 1982; 68:915-918.

The risk of developing coronary heart disease is clearly related to antecedent blood cholesterol levels. Interest in the predictive value of cholesterol levels for cancer incidence has arisen for several reasons: to identify for preventive purposes groups at high risk of cancer, to search for clues to cancer causation and pathology, and to evaluate the concern that the manipulation of blood lipid levels to decrease the risk of one disease may unfavorably alter the risk of another disease.

Several investigators (*1-10*) have explored the cancer-cholesterol relationship mostly focusing on mortality and using populations originally involved in the study of cardiovascular disease. These populations varied in age, sex, and racial distributions. The studies also varied in method of subject ascertainment, in length of follow-up, in emphasis on cancer incidence versus mortality, and in attention given to specific cancer sites. Here we report the relationship between the levels of plasma lipids and relative weight and the cancer incidences in a rural Iowa population.

METHODS

The subjects, 20-94 years old, were residents of Cedar County, Iowa, and participants in one of 10 collaborative LRC population studies supported by the National Heart, Lung, and Blood Institute, Bethesda, Md. All persons were studied by standardized procedures previously described (*11*). After a community publicity and information effort, we ascertained and enumerated the subjects by using current telephone directories. Eligible subjects, 25-59 years of age, were then invited to one of nine community screening clinics where, after an overnight fast, blood was drawn for plasma cholesterol and triglyceride determinations by standard LRC methods (*12*). Height and weight (without coats and shoes) were measured, and the patients' histories were obtained, though the occurrences of prior cancers were not specifically queried. Persons less than 25 and more than 59 years old, not specifically invited but attending the screening clinics in response to publicity, were treated in the same manner and included in this report if they met county residency requirements. Overall, 70% of enumerated persons participated in the screening activity. All were white.

Subjects were initially screened between July 1973 and December 1975. Beginning in 1973, a statewide cancer incidence registry was established in Iowa as part of the Surveillance, Epidemiology, and End Results Program of the National Cancer Institute (*13*). The registry records all incident cancers except nonmelanoma skin tumors and registration is thought to be more than 99% complete. Participants in the LRC survey were linked by name, address, sex, and birthdate to subjects in the cancer registry files through January 1980, an average of nearly 6 years of follow-up. Mortality surveillance was maintained by linkage with statewide death record computer tapes and surveillance of local obituary notices. A 15% random sample of the cohort is being followed annually by active surveillance for another study, revealing that, as of 1980, 96% of the living study subjects were still within the State, thus assuring nearly complete follow-up. No attempt was made to ascertain the status of subjects leaving the State.

The State of Iowa also had complete ascertainment of incident cancers in 1969-71 as part of the Third National Cancer Survey (*14*). Our study cohort was also linked to this data base in a manner similar to that reported above to detect participants with cancers diagnosed 1969-71, prior to lipid study.

Each subject with neoplasm developing after lipid screening was matched to another control member of the cohort not known to have a cancer or to have died at the time of the primary tumor occurrence. Controls were matched to cases by age within 1 year, by sex, by community screening site, and by nearest date of screening. In no instance did a significant difference in mean years of education or distri-

bution of occupations occur between any case and control analytic group. Those persons with documented cancers occurring prior to the screening activity were matched to a control subject in the same manner as above. Two subjects with separate cancers occurring both before and after lipid screening were excluded from analysis. Means of lipid levels and relative weight (expressed at the Quetelet Index: wt/ht^2×1,000) were compared with the use of paired *t*-tests.

RESULTS

On linking study subjects to the 1969–71 cancer register, 17 men and 37 women were found to have documented cancers prior to lipid screening. In general their lipid levels were higher than those of the matched controls, but significantly so only for cholesterol levels in men. Sex-specific relative weights were similar between these patients and controls. The subjects with cancers occurring before screening were excluded from further analysis.

Table 1 shows the age and sex distributions of the study cohort at the time of lipid measurement and the number of incident cancers over the surveillance interval. A total of 131 cancers were detected after lipid screening from a total of 5,565 persons. The distribution of neoplasms by site is shown in table 2.

Table 3 shows the overall sex-specific mean lipid levels and relative weight for the 131 persons with incident cancers and for their matched controls. Male patients had lower mean cholesterol and triglyceride levels and female patients higher lipid levels than did their respective controls, but none of the differences was significant. Examination of subjects according to age at screening revealed that the magnitude of the sex-specific lipid differences persisted for those less than 60 years of age, with a mean cholesterol level in female cancer patients significantly higher than that in the controls (table 3). Also, in the younger age group, the mean relative weight of the cancer patients was significantly lower in both sexes. Differences in mean lipid levels and relative weight were generally diminished or absent in the older age group. In these and subsequent analyses, no significant patient–control differences in mean triglyceride levels were found in any analytic category, though these levels in general paralleled cholesterol levels.

TABLE 1.—*Age and sex distributions of the study cohort and number of incident cancers*

Table 4 shows mean lipid levels and relative weight according to the interval between screening and cancer occurrence. The lower cholesterol levels for male cases seen in table 3 were also present for those with cancer occurring within 24 months of screening, but this difference diminished in subjects with cancer onset more than 24 months after screening. In contrast, the elevated mean cholesterol levels in female cases persisted and were not related to the interval between screening and disease onset. In all categories, cancer patients had a lower mean relative weight than did controls, with differences being significant for the longer screening interval.

[a] Includes 32 patients with breast cancer, 3 patients with uterine corpus cancer, and 5 patients with ovarian cancer.

[b] $P<0.05$.

[c] Includes 6 patients with lung cancer, 3 patients with laryngeal cancer, and 3 patients with bladder cancer, all but 1 in males.

Though the number of cancers at specific organ sites was limited, some specific sites and site groups were examined (table 5). No significant differences in mean lipid levels or relative weight were seen between cases and controls for colon–rectal or prostate cancers. Women with gonadal hormone-related cancers (breast, uterine corpus, and ovary) had a significantly higher mean cholesterol level than the controls. The 32 subjects with breast cancer had a mean cholesterol level 11 mg/dl higher than that of their controls, a marginally significant difference ($P<0.06$). Subjects with smoking-related cancers (11 males out of 12 subjects) had a significantly lower mean cholesterol level and relative weight.

DISCUSSION

As noted above, there are several important reasons for exploring the association of blood lipid levels with the subsequent development of cancer. Our findings agree with earlier published reports in some respects but differ in other respects.

None of the prior studies available to us explored blood triglyceride levels. We found no statistically significant relationship of triglyceride to cancer incidence in any analytic category, perhaps in part due to the number of study subjects and to the greater variance of such levels. However, mean triglyceride levels tended to vary in the same direction as that of the cholesterol levels, and further exploration of triglyceride alterations may be of value.

Males with cancers occurring after lipid screening had a mean plasma cholesterol level about 10 mg/dl lower than that of the matched controls, a finding most prominent for men under 60 years of age at the time of screening but less so for the older age group. Similar findings for incident cancers among males were reported in the Framingham (*5*) and Evans County studies (*4*), but neither study reported separately results for various age groups. Possibly, blood cholesterol is differentially predictive for cancer at different age groups as it is for coronary heart disease. Other available studies (*3, 6–10*) focused solely on mortality.

We found no significant alteration in cholesterol levels associated with colon–rectal or prostate cancers, but the number of subjects was small. Williams et al. (*5*) and Rose et al. (*2*) have reported that cholesterol levels are significantly and inversely associated with the development of colon cancer, but evidence exists that these levels are related to tumor staging and may not necessarily precede tumor development (*15*). When smoking-related cancers (lung, laryngeal, esophageal, and bladder) were considered together, the mean cholesterol level was significantly lower than that among controls.

In our study, female cancer patients had mean cholesterol levels generally higher than those of their matched controls. The mean cholesterol level was 18.7 mg/dl higher among cancer patients less than 60 years of age at screening ($P<0.05$) but only 2 mg/dl higher (not significant) for those 60 years and older when compared to the mean cholesterol level of their respective controls. The Framingham (*5*) and Evans County (*4*) studies evaluated women and found no important or significant cholesterol–cancer association. To our knowledge no other study has reported age-specific differentials in this association among women and, as in studies of males, the suggestion arises that cholesterol–cancer relationships are age-dependent. The elevated cholesterol levels in younger female patients were limited to patients with cancers at the hormone-related sites: breast, uterine corpus, and ovary. Mean differences in cholesterol levels between female patients and controls, excluding patients with cancers at these hormone-related sites, were negligible (results not shown). The higher mean cholesterol levels for the 32 breast cancer patients alone were only marginally significant, and results from other studies with reference to breast cancer are conflicting. Boyd in (*16*) reported findings similar to our own, whereas Friedman (*17*) reported no association between cholesterol levels and breast cancer incidence. Kark et al. (*4*) reported a small but insignificant decrease in cholesterol levels in breast cancer patients in Evans County. Dyer et al. (*7*) reported a significantly higher mean cholesterol level among women dying of breast cancer than among women alive 5 years after lipid screening. Cholesterol levels have also been inversely related to breast cancer survival (*18*). In our study mean cholesterol levels were higher among patients with breast cancer and other hormone-related cancers, though the mean relative weight was lower when compared to that of controls. Clearly, this issue requires further exploration.

For the entire population and for each sex, we found a lower mean relative weight at screening in those destined to develop neoplasms regardless of the blood-cholesterol associations. This finding has been described previously in reference to the natural history and metabolic consequences of cancer (*19*). For investigators exploring the causal significance of lipid-cancer associations, taking ponderosity into account seems important.

Some methodologic findings emerged in describing the lipid-cancer relationships. Several populations, including our own, were originally used for the study of cardiovascular disease. Hence we did not ask our subjects at screening whether they had had a previous cancer. By retrospective linkage with the tumor registry, we discovered that, at a minimum, 1% of our subjects had a documented cancer before the cohort was assembled. Not knowing this could lead to misclassification of subjects and could alter the study findings. However, for middle-aged cohorts, the likelihood of prior cancers is probably small.

We found lower mean cholesterol levels among male cases to be prominent only among those cases occurring within 24 months of screening, which has been suggested previously by Rose et al. (*20*) who dealt with early versus late cancer mortality in men. The Paris study also showed that cancer-associated cholesterol differentials gradually disappeared with increasing survival interval after incidence (*3*). However, in Evans County, patients with cancer emerging within 12 months of screening had slightly higher mean cholesterol levels than did the general population, in contrast to the lower cholesterol levels seen in subjects with cancers emerging more than 12 months after screening. In our study, the positive cholesterol-cancer association in women did not diminish with increasing interval between screening and disease incidence. This sex-specific difference may reflect differential cancer sites, clinical stage, or biologic impact on the host. No other studies were available to contrast this observation.

Our report was not intended to explore further the biologic meaning of the lipid-cancer associations. Exploring causal mechanisms for the emerging associations in this study may require knowledge of environmental variables such as diet, caloric expenditure, and alcohol and tobacco use—data not available for most of our cohort. A search for pathophysiologic explanations for such associations would require exploration of lipid effects on competing causes of morbidity and mortality and would require separate consideration of each anatomic site and histologic type of neoplasm, inasmuch as the biology of each may be quite different. Ultimately, however, the exploration of the blood lipid-cancer associations and their causal importance in populations is important for understanding lipid-related summary risk status and the effects of specific lipid interventions.

High Cloning Efficiency of Human Lymphoid Cells in Agarose Without Feeder Layers[1,2]

Kathleen N. Ayres[3,4,5]

ABSTRACT—A protocol has been developed that consistently gives high cloning efficiencies for human lymphoid cell lines (lymphoblastoid and lymphoma) in agarose without the use of feeder layers. This procedure utilizes a cloning medium that contains horse serum, α-ketoglutarate or oxalacetate, and high levels of glutamine.—JNCI 1982; 68:919–923.

Cloning assays have become vital for the measurement of cellular mutation, transformation, and survival after treatment with various drugs or DNA-damaging agents and for the selection of somatic cell hybrids after cell fusion. Human lymphoid lines have long been used for these assays because they are easy to maintain in suspension culture, retain a near-diploid karyotype, and unlike human fibroblasts have an unlimited life-span (*1*). The purpose of this article is to report a protocol for cloning human lymphoid cells. The protocol does not use time-consuming feeder layers and, for the cell line Raji, has given cloning efficiencies as high as 83% (*2*), with 50% being obtained routinely. Furthermore, the optimized cloning medium contains much less FCS (0–5%) than that used previously, a definite advantage if one considers the present exorbitant price of FCS.

Our goal was to find a system that could be used for the isolation of drug-resistant cell clones and hybrid cell clones as well as for survival curves and mutation assays. Since we wanted to be sure that all the cells in the clone were derived from a single cell, we opted for growth in agarose (*3–5*) rather than growth in mitrotiter plates (*6*). Cloning in agarose has the disadvantage that it may select for certain cell types (*4*). Conversely, the microtiter method is more likely to allow metabolic cooperation between cells when more than one cell is seeded per well, thus yielding misleading survival curves. In addition, analysis of microtiter plating experiments can involve statistical methods that are less direct than those required by agarose cloning.

MATERIALS AND METHODS

Cells.—Cultures of L33-6-1 [a lymphoblastoid line isolated from a patient with infectious mononucleosis by Dr. P. R. Glade and subcloned by Sato et al. (*7*)], Raji [a Burkitt's lymphoma-derived cell line established by Pulvertaft (*8*)], and HH-4 [a lymphoblastoid line derived from WI-L2 by Skopek et al. (*9*) and originally isolated from a patient with spherocytosis] were provided by Dr. J. Littlefield (The Johns Hopkins University, Baltimore, Md.), Dr. P. Gerber (National Institutes of Health, Bethesda, Md.), and Dr. W. G. Thilly, respectively. Using the procedure of DelGiudice and Hopps as described by McGarrity (*10*), Bioassay Systems (Cambridge, Mass.) found these cultures to be free from mycoplasma contamination. The cells were routinely grown in RPMI-1640 medium, without antibiotics, supplemented with 17% FCS and 2, 4, or 6 m*M* glutamine as dictated by the experimental conditions. Once a week, the stock cultures were diluted to 0.4×10^6 cells/ml with fresh medium and then incubated at 37°C in a humidified atmosphere of 95% air and 5% CO_2.

Cloning.—Our cloning protocol is a modification of the cloning method of Sato et al. (*7*) with the omission of the feeder layer and the substitution of Sea Plaque agarose (Marine Colloids, Inc., Rockland, Maine; control lot #12978), which gels at a lower temperature (<30°C) than the Seakem agarose (36°C) originally used by Sato et al. (*7*). Seventeen days before a cloning experiment, a stationary culture (7-day culture) was diluted to 0.4×10^6 cells/ml. It was diluted in a similar fashion again on the 7th, 14th, 15th, and 16th days of culture and cloned in agarose on the 17th day. For plating of the cells, a 2.5-ml bottom layer of a 0.24% agarose–medium mixture was poured per 60-mm culture dish, and the dishes were incubated in a cold room at 0–4°C for 15 minutes. The dishes were then either used directly or stored (≤1 wk) until the day of use. To obtain the 0.24% agarose, 0.24 g of agarose was added to 10 ml of 0.9% saline and autoclaved for 15 minutes at 120°C. The agarose–saline mixture was immediately diluted tenfold with warm medium in a water bath (35–36°C). On the day of plating, 0.2 ml of medium containing the desired number of cells was mixed with 2.0 ml of a 0.22% agarose–medium mixture and poured gently over the bottom layers. The 2.0-ml aliquots were mixed with the cells in blood-dilution tubes in a water bath (35–36°C). The plates were again placed at 0–4°C for 15 minutes and subsequently incubated at 36–37°C at 90–100% humidity and 6.0–6.5% CO_2 for 1 month. Once the plates are poured, they should not be agitated because this agitation will interfere with the gelling process. After plating, random dishes could be selected and scanned at 100–200× to make sure that the cells plated were single

[5] I thank Dr. W. G. Thilly (Massachusetts Institute of Technology, Cambridge, Mass.), who suggested that α-ketoglutarate might improve cloning efficiencies of lymphoid cells. I acknowledge Dr. Bernard Strauss (The University of Chicago) who extended the hospitality of his laboratory for the duration of this work. I also thank Ms. M. Chambers and Mrs. B. Neal, The University of Chicago, for technical assistance.

cells and not clusters of cells. Each dish was fed 0.5 ml of cloning medium the following day and at weekly intervals thereafter. Colonies were visible at 2 weeks and scoreable between 3 and 4 weeks (depending on the cell line). Colonies could then be isolated with the use of a Pasteur pipette and dispersed into 0.5 ml of medium in blood-dilution tubes.

Materials.—All sera used for cloning and general stock maintenance were heat inactivated at 56°C for 30 minutes. The FCS, premium HS, and RPMI-1640 (without glutamine) were obtained from Kansas City Biological, Inc., Lenexa, Kan. α-Ketoglutarate, α-ketobutyrate, oxalacetate, and sodium pyruvate were obtained from Sigma Chemical Co., St. Louis, Mo., whereas the glutamine was obtained from Grand Island Biological Co., Grand Island, N.Y., and the β-mercaptoethanol was from Eastman Kodak Co., Rochester, N.Y. We made a 0.2-*M* stock of glutamine and 0.1-*M* stocks of α-ketoglutarate, α-ketobutyrate, oxalacetate, and sodium pyruvate by dissolving these compounds in RPMI-1640 medium and adjusting the pH to 7.2. Aliquots of these stocks were kept frozen and added to the medium on the day of use. For these experiments, cells were plated in 60-mm Corning tissue culture dishes (Corning Glass Works, Corning, N.Y.) at 100 cells/dish.

RESULTS

First attempts to clone these lymphoid cells with the use of the standard growth medium (17% FCS in RPMI-1640 medium containing 2 m*M* glutamine) produced cloning efficiencies of approximately 5% for Raji and 0.1% for L33-6-1. We then found that logarithmic cells produced higher cloning efficiencies than cells from a stationary culture, and we devised a dilution scheme that yielded a high number of cells in logarithmic growth. All of the experiments discussed in this paper have used this dilution scheme. Variations may also succeed, but if the cells are diluted too frequently without being allowed to go through a stationary phase, some lymphoid cultures die out and, in particular, Raji and L33-6-1 do not give high cloning efficiencies. The dilution scheme described in "Materials and Methods" gave the highest cloning efficiencies in our laboratory. In the experiments reported here, we also carefully controlled factors such as the agarose lot, pH, CO_2 concentration, and humidity.

Table 1 shows the cloning efficiencies obtained after growth in standard working medium plus 2 m*M* glutamine, followed by plating in various supplemented media. The results in table 1 are typical of those obtained in several similar experiments. The highest cloning efficiencies were obtained in media that contained either 15% HS and no FCS (medium D) or a mixture of 10% HS and 5% FCS (media C, H, I, J, and A). A comparison of media A, B, and C, which were identical with the exception of the molarity of glutamine, showed that the highest molarities of glutamine produced the highest cloning efficiencies. The results for media A, F, H, and I suggested that α-ketoglutarate, oxalacetate, and sodium pyruvate each yielded a significant increase in the number of clones (compared to medium F which contained none of these ingredients). α-Ketobutyrate (not a tricarboxylic acid cycle intermediate) may have produced some increase in the number of clones compared to the number produced in medium F, but the clones were often diffuse and difficult to count as well as being quite small (*see* fig. 1). Colonies that grew up in the presence of α-ketoglutarate or oxalacetate (tricarboxylic acid cycle intermediates) tended to appear more rapidly and produce more uniformly sized colonies than colonies that grew up in media without one of these supplements.

The cloning efficiencies depicted in table 1 were obtained after growth of the stock cells in RPMI-1640 supplemented with 17% FCS and 2 m*M* glutamine. Table 2 gives cloning efficiencies for a similar experiment in which 6 m*M* glutamine was substituted for the 2 m*M* glutamine during the growth of stock cells. The results in table 2 are typical of those obtained in several similar experiments. All of the supplemented media tested in table 2 gave higher cloning efficiencies than their counterparts in table 1. Further improvements may possibly be obtainable by adjustment of

TABLE 1.—*Cloning efficiencies of Raji and L33-6-1 in agarose with various cloning media, after growth in 2* mM *glutamine*

[a] Medium for both growth and cloning was RPMI-1640 (without glutamine), which was made up from powder and adjusted to pH 7.2. Various cloning media (A–J) were obtained by the addition to RPMI-1640 of the supplements listed in the left-hand column, where the units are % and m*M*. All FCS was from lot #308385 (Kansas City Biological, Inc.), and all HS was from lot #26079 (Kansas City Biological, Inc.). Before plating, both Raji and L33-6-1 were grown in RPMI-1640 plus 17% FCS and 2 m*M* glutamine and were kept in logarithmic growth by adherence to the dilution schedule described in "Materials and Methods."

[b] Cloning efficiencies were calculated from the average number of colonies counted on ten 60-mm plates for both Raji and L33-6-1 after plating Raji at 100 cells/dish and L33-6-1 at 200 cells/dish in each of the above media. Uncertainties quoted are standard deviations calculated from the numbers of clones. To minimize systematic errors in the comparison, we obtained the results simultaneously in one large experiment using common parental cell stocks.

TABLE 2.—*Cloning efficiencies of Raji in agarose with various cloning media, after growth in 6 mM glutamine*

Supplement	Cloning efficiencies with cloning medium[a]						
	K	L	M	N	O	P	Q
FCS, % (lot)	5 (#308385)	5 (#30004)	0	5 (#308385)	5 (#308407)	5 (#308385)	5 (#308385)
HS, %	10	10	15	10	10	10	10
Glutamine, m*M*	6	6	6	6	6	6	6
α-Ketoglutarate, m*M*	1	1	1	1	1	0	0
Pyruvate, m*M*	0	0	0	0	0	0	1
Oxalacetate, m*M*	0	0	0	1	0	1	0
Raji cloning efficiency, %[b]	45±2	47±2	51±2	46±2	39±2	48±2	40±2

[a] Conditions were the same as those in table 1 with the exception that three different lots of FCS were used (lot numbers are identified in the table) and that before plating, Raji was grown in RPMI-1640 plus 17% FCS and 6 m*M* glutamine. Cells were kept in logarithmic growth prior to plating by following the dilution schedule described in "Materials and Methods."

[b] Cloning efficiencies were calculated from the average number of colonies counted on ten 60-mm plates after plating Raji at 100 cells/plate in each medium. Uncertainties quoted are standard deviations calculated from the numbers of clones. To minimize systematic errors in the comparison, we obtained the results simultaneously in one large experiment using common parental cell stocks.

the glutamine supplement to the specific needs of individual cell lines.

When media K, L, M, and O were compared, 15% HS again produced the highest cloning efficiency, whereas cloning efficiencies of the other three media varied with the FCS lot. When the mixture of 5% FCS and 10% HS was used for cloning, we repeatedly observed this differential in cloning potential among lots of the FCS. The variability between lots of HS was not as great, perhaps because the HS was obtained from a single donor herd.

Although the differences in cloning efficiency produced by the addition of sodium pyruvate versus α-ketoglutarate are not large in table 2, they seem to be larger than those in table 1. In addition, visual inspection of colony growth showed that α-ketoglutarate and oxalacetate produced firm, rapidly appearing, rapidly growing colonies, whereas sodium pyruvate did not (*see* fig. 1). In addition to the experiments represented in the tables, we performed a separate set of experiments suggested by the results of Broome and Jeng (*11*), who reported that a thiol such as β-mercaptoethanol could have growth-promoting activity for lymphoid cells. Unfortunately, we found no beneficial effect from the addition of β-mercaptoethanol. At 5×10^{-5} *M* β-mercaptoethanol, the plating efficiencies of both Raji and L33-6-1 were almost identical between control and β-mercaptoethanol plates.

In summary, the cloning efficiencies that we have been able to obtain using either 15% HS or 10% HS and 5% FCS plus additional supplements of α-ketoglutarate or oxalacetate and 6 m*M* glutamine have been much higher than those obtained previously. We have obtained routine cloning efficiencies of 50% for Raji (range=45–83%) (*2*), of 20% for L33-6-1 (range=10–35%), and of 35% for HH-4 (range=15–50%).

DISCUSSION

Although some consider cloning of cells to be more art than science, large increases in cloning efficiencies may be obtained for a number of cell lines if important parameters are systematically optimized. We found the single most important factor to be the substitution of HS for the FCS that had been used previously. Components of HS have been found essential for colony formation of mouse primitive red blood cells as well (*12*). However, the combination of 5% FCS and 10% HS seemed to give more repeatedly reliable results inasmuch as the plates tended to become acidic less rapidly. Acidity makes the agarose less firm, and the clones become unscoreable. Hence our preferred cloning medium composition is 10% HS, 5% FCS, 6 m*M* glutamine, and 1 m*M* α-ketoglutarate or 1 m*M* oxalacetate in a base of RPMI-1640.

This procedure has allowed the cloning of lymphoblastoid (L33-6-1 and HH-4) as well as lymphoma (Raji) cell lines. At present, we have no data on the cloning efficiencies of recently isolated lymphoid cell lines. However, many lymphoid lines that tend to clump in stationary phase can still be cloned by means of this procedure, because the dilution scheme establishes logarithmic growth where the clumps of cells are usually smaller and dispersible by gentle shaking. We have not determined whether α-ketoglutarate and oxalacetate promote cloning because they are intermediates in the tricarboxylic acid cycle or because they can ultimately be converted to glutamine. They may exert their activity because of their interaction with serum components, as demonstrated by McKeehan and McKeehan (*13*). However, α-ketobutyrate (not a tricarboxylic acid cycle intermediate) is not as effective as are α-ketoglutarate and oxalacetate in enhancing size and discreteness of clones. Glutamine has been shown to be a major source of energy for some cells in culture, including lymphoma cells (*14–16*). However, we have obtained the glutamine enhancement of cloning with both lymphoma and lymphoblastoid cells.

We have used this protocol to obtain dose-response curves to 6-thioguanine, ouabain, diphtheria toxin, and neocarzinostatin and to obtain survival curves after treatment with methyl methanesulfonate, *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, and *N*-acetoxy-2-acetylaminofluorene. This protocol has also been used for selection of hybrid cells with the use of both the HAT-selection system of Littlefield (*17*) and the HAT–ouabain-selection system (*18*, *19*).

Mortality Among Workers in a Nickel Refinery and Alloy Manufacturing Plant in West Virginia[1,2]

Philip E. Enterline, *Ph.D.,*[3] *and* **Gary M. Marsh,** *Ph.D.*[3,4]

ABSTRACT—Workers from a nickel refinery at Huntington, W. Va., which received a nickel matte from smelters in Ontario, Canada, during 1922–47 were studied for excesses in sinonasal and lung cancers. Other workers who were in a nickel alloy production plant operated in conjunction with the refinery but who did not work in the refinery were also studied. Evidence is presented on the existence of a nasal cancer hazard and possibly a lung cancer hazard among workers employed in the nickel refinery. Two of these workers developed a sinonasal cancer. Evidence of a respiratory cancer hazard in other parts of the plant before or after 1947 is weak, and the observed results could be due to chance variations from the mortality experience of the standard reference populations. Among nonrefinery workers hired while the nickel refinery was in operation, 2 employees had a probable sinonasal cancer. The first employee worked in a high-temperature conversion process where nickel carbonate was decomposed to nickel oxide, and the second employee is believed to have done maintenance work in the plant where this process was used. For both cohorts combined there were slight overall excesses in lung, stomach, and prostate cancers with some evidence of a dose-response relationship for these cancers.—JNCI 1982; 68:925–933.

Nickel has been mined and smelted in the Sudbury region of Ontario, Canada, since the last century. A copper–nickel matte—essentially a mixture of Cu_2S and Ni_3S_2—was shipped from that area to nickel refineries in various parts of the world. Epidemiologic studies at four of these refineries (Clydach, Wales; Kristiansand, Norway; and Port Colborne and Copper Cliff, Canada) have shown an excess in cancers of the lung and nasal sinuses [(*1–3*); Sutherland RB: Mortality among sinter plant workers. Toronto: Report of the Division of Industrial Hygiene, Ontario Department of Health, 1969].

Matte from one Sudbury smelter was also shipped to a nickel refinery at Huntington, W. Va. The refinery, owned by INCO Limited, was operated in conjunction with the manufacture of wrought forms of nickel-containing alloys. The refinery consisted of two departments: 1) calcining and 2) melting and casting.

The calcining department operated from 1922 to 1947. There, high copper–nickel matte from Sudbury was crushed, ground, and oxidized at 1,200°C in four gas-fired calciners to produce copper–nickel oxide suitable for the manufacture of Monel alloy. Four more calcining furnaces were built early in 1941 to oxidize low copper–nickel matte produced mainly in New Caledonia from oxide nickel ore, although some was also received from Sudbury. The calcining department also reduced nickel oxide from Canada to nickel metal and occasionally decomposed copper–nickel carbonate from the plant's pickling operations to copper–nickel oxides. Concentrations of total particulates were very high where the matte was crushed, ground, and handled (50–500 mg/m^3), whereas concentrations around the calciners were much lower (10–20 mg/m^3). Concentrations of airborne nickel in these areas were estimated to range from 20 to 350 mg Ni/m^3 and from 5 to 15 mg Ni/m^3, respectively (International Nickel Co., Ltd.: Nickel and its inorganic compounds. Report submitted to the National Institute for Occupational Safety and Health, Oct. 1976).

The melting and casting department operated gas-fired open-hearth furnaces and electric arc furnaces to melt various nickel-containing alloys and cast them into ingots. These ingots were then forged, rolled, drawn, or otherwise worked into various wrought forms of nickel-containing alloys.

This is a report of an investigation of the mortality experience of workers employed for 1 year or more in the refinery at the Huntington plant. The investigation was undertaken to ascertain whether these workers experienced an increased incidence of cancers of the lung and nasal sinuses as did refinery workers elsewhere who oxidized nickel matte in dusty environments. This report also describes the mortality experience of other workers who were employed at the Huntington plant and who were exposed to airborne nickel in various forms but who either did not work in the refinery or worked there for less than a year. This part of the study was undertaken to investigate whether an increased incidence of respiratory cancer was associated with the manufacture of wrought forms of nickel-containing alloys.

MATERIALS AND METHODS

Since the calciners at Huntington were torn down near the end of 1947, we decided to examine the company rolls as of January 1, 1948. Some 1,855 men on the payrolls that day had been hired before 1947 and had thus accumulated at least 1 year's service while the calciners were still in

ABBREVIATIONS USED: ICD=International Statistical Classification of Diseases, Injuries, and Causes of Death; SMR=standardized mortality ratio(s).
